## 1. Summary

Cancer is the second most frequent cause of death in developed countries. The most dangerous ability of cancer cells of a primary tumor is to invade adjacent or distant organs. This process, known as metastasis, represents the main cause of death from cancer. Among all the different cancer types, colorectal cancer is the second cause of death by malignant tumors in both Europe and US.

The carcinogenic process in the colon starts when genetic and/or epigenetic alterations accumulate in normal tissue cells. Some of the mutations affect key genes involved in signal transduction, apoptosis, and DNA repair such as mismatch repair. In most cases, the transformation process, which begins in the epithelial crypts, seems to result from qualitative, quantitative, and spatial subversion of the Wnt signaling pathway, the physiological regulator of epithelial homeostasis. These early events trigger the transformation of normal cells into dysplastic cells, which proliferate and form benign tumors, called **adenomas**. Additional sequentially ordered mutations arise to end up with malignant lesions, named **cancer**. Thus, colon cancer progression can be divided in three critical stages; i) the normal to adenomatous cell transition, ii) the progression from adenoma to carcinoma, and iii) the appearance of metastasis. Clinical intervention, based on the biological knowledge of the different stages acquired during the last three decades, could greatly improve the management of this disease.

In an attempt to discover genes responsible for the initial steps of epithelial transformation, we performed a comprehensive transcriptome analysis of colorectal adenomas (**see Results and Appendix I**).

Among the most over-expressed genes in adenomas, we found *KIAA1199*, a gene with unknown function. In normal tissue, both the RNA and protein were expressed at the bottom of the intestinal crypts where the proliferative compartment is located. Interestingly, we saw a striking over-expression all over the adenomatous tissue, particularly in the cytoplasm facing the crypt lumen and in/around the mucin vacuoles of goblet cells. The over-expression persisted during the transition from low-grade dysplasia with goblet-cell differentiation to high-degree dysplasia in which this differentiation was no longer apparent. *KIAA1199* mRNA and protein were also over-expressed in advanced colon cancers.

These data, taken together with other findings obtained during a collaborative work with Prof. Hans Clevers' laboratory, Hubrecht Institute, Netherlands Institute for Developmental Biology, Utrecht (**see Results and Appendix II**), suggested *KIAA1199* as a novel biomarker of colorectal tumors, as well as a new target gene of the Wnt signaling pathway.

Briefly, we compared the list of up-regulated genes in adenomas and carcinomas (compared with normal mucosa), with that of genes down-regulated upon stable transfection of LS174T and DLD1 colorectal cancer cell lines with dominant negative TCF1 or TCF4 (dnTCF1 and dnTCF4), or beta-catenin siRNA. These dnTCFs block the formation of a transcription complex composed of beta-catenin and the DNA-binding proteins of the T cell factor/lymphoid-enhancing factor (TCF/LEF) family. We assumed that genes common to both lists might be putative Wnt targets. This combined analysis of microarray data for tissues and cell lines placed *KIAA1199* at the top of the common gene list.

For a better clinical management of tumors, it is essential to know the different molecular characteristics they acquire during transformation. Not all colorectal cancers exhibit the same features in terms of growth rate, aggressiveness, prognosis, etc. For example, defects in one of the DNA mismatch repair genes are crucial events for cancer initiation and progression in the colon and other organs (for details see 3.2.3.). These defects confer characteristic phenotypes to the tumors: high level DNA microsatellite instability, conspicuous lymphocytic infiltration, preferential location in the proximal colon, and better prognosis. It has been generally accepted that the better prognosis of mismatch repair deficient colon cancers is related to the conspicuous infiltration of CD8+ lymphocytes, but the molecular aspects of this histological feature have not been studied. In a microarray analysis of mismatch repair deficient cancers, we have identified **4-1BBL**, a gene playing a key role in the anti-tumor response, as one of the most prominently over-expressed genes in these tumors. Its over-expression was also confirmed at the protein level with flow cytometry. We have proposed that this ligand presented by neoplastic cells could be a target of 4-1BB present on CD8+ cytotoxic lymphocytes. This finding could also be explored to identify novel approaches for the treatment of this subgroup of colon cancers. We also showed that MSI could conceivably be responsible for the decreased transcript levels of genes containing 5'-UTR or coding- region microsatellites. Alterations in the 5'-UTR could diminish transcription efficiency, whereas coding-region MSI would lead to nonsense-mediated decay of the RNA transcript. In contrast, genes whose 3'-UTRs contained long mononucleotide repeats generally displayed increased expression in MMR-deficient settings, and the 3 genes of this type tested for MSI all displayed repeat shortening. The fact that in reverse-transcription polymerase chain reaction the microsatellite-containing tracts of the 3'-UTRs of these genes (but not their coding regions) were amplified much more efficiently in MMR-deficient cells is difficult to explain, but recent evidence suggests that poly(U)-tract length can affect RNA stability and processing and translation efficiency (**see Results and Appendix III**).

Another aspect that can affect cancer incidence is the intrinsic molecular and biological nature of the normal tissue of origin.

For example, in the lower gastrointestinal tract, concretely in the ileum (the last part of the small intestine) and in the colon (the main part of the large bowel), cancer rates are surprisingly different showing an adenocarcinoma incidence in the ileum around 25 times lower than in the colon, despite the fact that both tissues have high proliferative rates. This striking difference motivated us to perform a comparative transcriptome analysis of these two normal tissues (**see Results and Appendix IV**).

Although this work is still ongoing, preliminary results showed interesting transcriptional differences in i) genes related to cell differentiation and cell proliferation, ii) transcription regulators, iii) Wnt-signaling pathway genes, and iv) apoptosis.

In this last group of genes, two pro-apoptotic genes members of the cell death-inducing DFFA-like effectors family, **CIDEB** and **CIDEC**, were found significantly under-expressed in colon compared with ileum. In addition, transcript levels for these genes were further down-regulated in colon adenomas and adenocarcinomas. These findings raise the question of whether the down-regulation of

pro-apoptotic genes in normal colon might be related to a higher predisposition to cellular transformation in this organ.

In conclusion, during my PhD studies, we have 1) characterized the transcriptome of normal epithelia of the lower gastrointestinal tract, and of benign and malignant tumors of the colon, 2) identified novel molecular markers of adenomatous transformation and of advanced colon cancer with defective mismatch repair system, 3) identified new putative Wnt target genes in colon adenomas and carcinomas.

We strongly believe the data we produced could give important hints to better understand colon carcinogenesis and to improve its clinical treatment.

## 2. Zusammenfassung

Krebs ist die zweithäufigste Todesursache in entwickelten Ländern. Die wohl gefährlichste Eigenschaft von Krebszellen eines primären Tumors ist es, in umliegende oder entfernte Organe vorzudringen. Dieser Prozess, bekannt unter dem Begriff Metastasieren, ist der Hauptgrund für den tödlichen Verlauf von Krebs. Unter all den verschiedenen Typen ist der kolorektale Krebs die zweithäufigste Todesursache durch bösartige Tumoren, und dies sowohl in Europa als auch in den US.

Durch die Ansammlung von genetischen und/oder epigenetischen Veränderungen in normalen Gewebezellen startet der karzinogene Prozess im Dickdarm. Einige der bekannten Mutationen betreffen Gene, welche Schlüsselfunktionen in Signaltransduktion, Apoptosis und DNA-Reparatur (z.B. Fehlpaarungsreparatur (MMR)) einnehmen. Der Transformationsprozess, welcher im Krypten-Epithel beginnt, scheint in den meisten Fällen das Resultat qualitativer, quantitativer und räumlicher Zerstörung des Wnt-Signalweges zu sein. Der Wnt-Signalweg ist der physiologische Regulator der Epithel-Homöostase. Diese frühen Ereignisse lösen die Transformation von normalen Zellen in fehlgebildete, dysplastische Zellen aus. Letztere proliferieren und bilden gutartige Tumoren, sogenannte **Adenome**. Entstehen weitere sequenziell angeordnete Mutationen führt dies zu bösartigen Läsionen, sprich Krebs. Deshalb kann das Fortschreiten von Dickdarmkrebs in drei kritische Phasen unterteilt werden: i) Transition von normalen Zellen zu adenomatösen Zellen, ii) der Verlauf von Adenoma zu Karzinoma und iii) das Auftreten von Metastasen. Durch das fundierte biologische Verständnis dieser verschiedenen Phasen konnten die klinischen Behandlungsansätze für die Krankheit in den letzten drei Jahrzehnten stark verbessert werden.

In einem Versuch, die für die initialen Schritte der Epithel-Transformation verantwortlichen Gene zu finden, führten wir eine umfassende Transkriptom-Analyse von kolorektalen Adenomen durch (**siehe Results and Appendix I**).

Als eines der am stärksten überexprimierten Gene in Adenomen entdeckten wir *KIAA1199*, ein Gen mit unbekannter Funktion. In normalem Gewebe wird sowohl die RNA als auch das Protein selber zuunterst in den Darm-Krypten exprimiert, dort wo sich das proliferative Kompartement befindet. Interessanterweise sahen wir eine markante Überexprimierung im gesamten adenomatösen Gewebe, speziell in dem dem Krypten-Lumen zugewandten Zytoplasma und in/um die Muzin-Vakuolen der Becherzellen. Die Überexprimierung bestand von der Transition von low-grade Dysplasie mit Becherzell-Differenzierung bis hin zur hochgradigen Dysplasie bei welcher diese Differenzierung nicht mehr vorhanden war. Die mRNA und das Protein von KIAA1199 waren auch in fortgeschrittenem Dickdarmkrebs überexprimiert.

Diese Daten, zusammen mit den Resultaten aus der Kollaboration mit Prof. Hans Clever's Labor, Hubrecht Institute, Netherlands Institute for Developmental Biology, Utrecht (**siehe Results and Appendix II**), lassen den Schluss zu, dass KIAA1199 sowohl ein neuer Biomarker für kolorektale Tumore, als auch ein neues Zielgen des Wnt-Signalweges ist.

Kurz, wir verglichen die Liste der aufregulierten Gene in Adenom und Karzinom (verglichen mit normaler Mukosa) mit der Liste der abregulierten Gene nach stabiler Transfektion von LS174T und

DLD1 kolorektalen Krebszell-Linien mit dominant-negativem TCF1 oder TCF4 (dnTCF1 and dnTCF4), oder beta-catenin siRNA. Die dnTCFs verhindern die Bildung von Transkriptionskomplexen bestehend aus beta-catenin und den DNA-Bindungsproteinen der T cell factor/lymphoid-enhancing factor (TCF/LEF)-Familie. Wir vermuteten, dass Gene, die auf beiden Listen erscheinen, mögliche Wnt-Zielgene sein könnten. Diese kombinierte Microarray-Daten-Analyse für Gewebe und Zell-Linien rückte KIAA1199 an die Spitze der gemeinsamen Gen-Liste.

Um Tumoren in der Klinik besser behandeln zu können ist es unabdingbar, die verschiedenen molekularen Eigenschaften, welche durch Transformation entstehen, genau zu kennen. Nicht jeder kolorektale Krebs zeigt die gleichen Verhaltensweisen in bezug auf Wachstumsgeschwindigkeit, Aggressivität, Prognose etc. Zum Beispiel sind Defekte in einem an der Fehlpaarungs-Reparatur beteiligten Gen eine massgebliche Voraussetzung für den Beginn und das Fortschreiten von Krebs im Dickdarm und anderen Organen (für Details siehe 3.2.3.). Diese Defekte verleihen dem Tumor einen charakteristischen Phänotyp: ein hohes Niveau an DNA Mikrosatelliten-Instabilität (MSI), auffällige lymphozytäre Infiltration, bevorzugte Lokalisation im proximalen Dickdarm und bessere Prognosen. Es ist generell bekannt, dass die bessere Prognose von Fehlpaarungs-Reparatur-defizientem Dickdarmkrebs mit der auffälligen Infiltration von CD8+-Lymphozyten zusammenhängt, wobei die molekularen Aspekte dieser histologischen Eigenart nie studiert wurden. In einer Microarray-Analyse von Fehlpaarungs-Reparatur(MMR)-defizientem Krebs identifizierten wir das Gen **4-1BBL**, welches nicht nur eine Schlüsselrolle in der Anti-Tumor-Antwort spielt sondern auch eines der am stärksten überexprimierten Gene in diesen Tumoren ist. Die Überexprimierung dieses Genes wurde auch auf Proteinebene mittels Durchfluss-Zytometrie bestätigt. Wir könnten uns vorstellen, dass dieser Ligand von neoplastischen Zellen präsentiert wird und ein Ziel von 4-1BB sein könnte, welches wiederum auf zytotoxischen CD8+-Lymphozyten vorhanden ist. Diese Erkenntnis könnte auch dazu benutzt werden, neue Behandlungsansätze für diese Krebs-Untergruppe zu identifizieren. Wir konnten auch zeigen, dass MSI möglicherweise verantwortlich für die verminderte Transkription von Genen ist, welche Mikrosatelliten entweder im 5'-UTR-Abschnitt oder in den kodierenden Regionen beherbergen. Veränderungen im 5'-UTR-Abschnitt könnte die Transkriptions-Effizienz abschwächen, während Mikrosatelliten in den kodierenden Regionen non-sense mediated decay der RNA-Transkripte zur Folge haben könnte. Auf der anderen Seite zeigten Gene, welche 3'-UTR mit langen Mononukleotid-Wiederholungen enthielten, generell erhöhte Expressierung in MMR-defizienten Einstellungen. Drei auf MSI untersuchte Gene dieses Typs waren durch Verkürzungen in den Wiederholungen charakterisiert. Die Tatsache, dass in MMR-defizienten Zellen die Mikrosatelliten-enthaltenden Bereiche in den 3'-UTR-Abschnitten dieser Gene wesentlich effizienter mittels reverse-transcription polymerase chain reaction (RT-PCR) amplifiziert wurden, ist schwierig zu erklären. Neueste Erkenntnisse lassen aber vermuten, dass die Länge von poly(U)-Abschnitten die Stabilität, die Prozessierung und die Translations-Effizienz von RNA beeinflussen kann (**siehe Results and Appendix III**).

Die intrinsische molekulare und biologische Beschaffenheit von normalem Ursprungsgewebe ist ein weiterer Aspekt, welcher das Auftreten von Krebs bestimmen kann.

Als Beispiel: Obschon sowohl im Ileum (letzter Teil des Dünndarms, auch Krummdarm genannt) als auch im Dickdarm (auch Grimmdarm genannt) die Gewebe hoch-proliferativ sind, ist das

Auftreten von Adenokarzinomen überraschenderweise im Ileum zirka 25-mal seltener als im Dickdarm. Dieser markante Unterschied hat uns motiviert, eine vergleichende Transkriptom-Analyse von diesen beiden normalen Geweben durchzuführen (**siehe Results and Appendix IV**).

Obschon wir diese Arbeit noch nicht abgeschlossen haben, geben die ersten Resultate interessante Hinweise: wir beobachten transkriptionelle Unterschiede in i) Genen, welche mit Zell-Differenzierung und Zell-Proliferierung in Verbindung stehen, ii) Transkriptions-Regulatoren, iii) Genen des Wnt-Signalweges und iv) Apoptose.

In der letztgenannten Gruppe von Genen fanden wir zwei pro-apoptotische Mitglieder der cell death-inducing DFFA-like effectors-Familie, nämlich **CIDEB** und **CIDEA**. Verglichen mit dem Ileum waren beide deutlich unterexprimiert im Dickdarm. Dazu kommt, dass bei diesen Genen das Level der Transkripte in Dickdarm-Adenomas und Adenokarzinomen noch weiter abreguliert war. Die Frage stellt sich nun, ob Abregulierung von pro-apoptotischen Genen in normalem Dickdarmgewebe vielleicht mit einer höheren Prädisposition für zelluläre Transformation in diesem Organ verbunden ist.

Zusammenfassend kann man sagen, dass wir während meiner Doktorarbeit 1) das Transkriptom von normalem Epithel des unteren gastrointestinalen Trakts und von gut- und bösartigen Dickdarmtumoren charakterisiert, 2) neue molekulare Marker der adenomatösen Transformation und des fortgeschrittenen Dickdarmkrebs mit defektivem MMR-System identifiziert und 3) ebenso neue mögliche Wnt-Zielgene in Dickdarm-Adenomen und –Karzinomen identifiziert haben.

Wir glauben, dass unsere Daten wichtige Hinweise für ein besseres Verständnis der Dickdarm-Karzinogenese liefern und dadurch die klinischen Behandlungen verbessert werden können.

### 3. Introduction

According to the World Health Organization (WHO), the top-5 causes of human mortalism in developed countries are i) cardiovascular diseases, ii) cancer (malignant neoplasm), iii) cerebrovascular diseases (stroke), iv) chronic obstructive pulmonary diseases (emphysema, chronic bronchitis), and v) accidents (unintentional injuries).

On the other hand, the situation in developing countries is different because of shorter life span, due to the lower living standards (lack of potable water, food, and access to medicines) and deficient information and education. The shortest life span decreased the incidence of “developed diseases”, like cancer, associated with aging. In contrast, HIV-AIDS (on the top of the list) and parasitic diseases (such as diarrhea, malaria), pathologies under control in developed countries, are primary causes of death.

Cancer, being the second most frequent cause of death in developed countries, is a public health problem that costs thousands of billions every year. For this reason, its prevention, detection, treatment, and cure has become a topic of primary interest for thousands of research groups all over the world.

#### 3.1. Cancer

The term cancer encloses a vast group of diseases that can arise in almost any part of the body. The process by which cancer appears and develops is called carcinogenesis and it is characterized by the rapid and uncontrolled proliferation of cells and their capacity to invade adjacent tissues, or to be transported through the blood stream or lymphatic system to occupy distant tissues, in a process known as metastasis. Metastasis is the major cause of death from cancer.

Cancer risk is thought to be related to age because the increased and uncontrolled growth of the cells is caused by mutations in the DNA and DNA damage, more frequent in aging DNA. Although many mutations arise during DNA replication, there are many mechanisms to repair them and also many mutations are necessary for the transformation of a normal cell into a cancer cell. Mutations in the DNA are a result of the interaction between genetic factors of the host and external agents of different origin; physical (ultraviolet and ionizing radiation), chemical (asbestos, tobacco, alcohol...), or biological (virus, bacteria, and parasites) carcinogens. Cancers can be sporadic, most of them, or inherited, which then are called syndromes.

##### 3.1.1. Classification

The abnormal and disorganized growth in a tissue or organ, usually forming a distinct mass of cells, is called neoplasia or tumor. Tumors can be benign or malignant (cancer). Cancers can be classified according to the tissue origin of the tumor: carcinomas, lymphomas and leukemias, sarcomas, mesotheliomas, gliomas, germinomas, and choriocarcinomas.

**Carcinomas:** these malignant tumors are derived from epithelial cells and are the most common type of cancers. Carcinomas invade surrounding tissues and organs, and may spread to

lymph nodes and distal sites (metastasis). In this group we included breast, prostate, lung and colon cancers. They can be classified by their histopathological appearance:

*Adenocarcinomas* are malignant tumors originating in the epithelial cells of glandular tissues.

*Squamous cell carcinomas* show squamous cell differentiation. Squamous cell carcinoma is usually developed in the epithelial layer of the skin and sometimes in various mucous membranes of the body.

*Small cell carcinomas* are usually associated with the lung, though they can be associated with other topographies, such as in cervical cancer.

**Lymphomas** and **Leukemias**: these are malignant tumors derived from blood and bone marrow cells characterized by an abnormal proliferation of blood cells, usually white blood cells (leukocytes).

**Sarcomas**: are cancers that arise from connective tissue, or mesenchymal cells

**Mesothelioma**: tumors derived from the mesothelial cells lining the peritoneum and the pleura.

**Gliomas**: are primary central nervous system (CNS) tumors that arise from glial cells. The most common site of involvement of a glioma is the brain, but they can also affect the spinal cord, or any other part of the CNS, such as the optic nerves.

**Germinomas**: are malignant tumors which most closely resemble germ line cells. These types of neoplasia are usually found in the testes or ovaries. Germinoma found outside these areas may be referred to as dysgerminomas.

**Choriocarcinomas**: are malignant and aggressive cancers of the placenta. They are characterized by early hematogenous spread to the lungs.

### 3.1.2. Worldwide incidence and death rates

In Europe and the United States of America (US), cancer incidence and death rates are very similar<sup>1, 2</sup>. Because of the increasing age of the population, the number of cancer cases will continue to increase every year, although the knowledge about these diseases and the mechanisms to prevent, detect, and treat them, have remarkably improved in the last decades.

In Europe, there were almost 3 millions new cancer cases in 2004<sup>1</sup> (Figure 1). The highest incidence percentages were registered for lung (13.2%), colorectal cancer (CRC; 13.0%), and breast (12.8%) cancers. The cancers with the highest mortality were lung (20%), CRC (11.9%), and stomach (8.1%). Dividing the statistics by gender, the most frequent cancers in men affected lung (19.5%), prostate (15.5%), and CRC (12.8%) whereas in women, breast (27.4%), CRC (13.3%), and uterus (9.9%) cancers were the most common malignant tumors observed. In terms of death rates, lung (27.9% and 9.8%, in men and women, respectively), CRC (10.7% and 13.3%, in men and women, respectively), prostate (15.5% in men), and breast (17.4% in women) cancers comprised top-3 for each gender.

**Cancer Incidence and Death Rates in Europe (2004)**

Incidence		Death	
Lung	13.2%	Lung	20.0%
CRC	13.0%	CRC	11.9%
Breast	12.8%	Stomach	8.1%
Prostate	8.2%	Breast	7.6%
Stomach	5.9%	Prostate	5.0%
Uterus	4.6%	Lymphoma	3.8%
Lymphoma	4.2%	Leukemia	3.1%
Oral Cavity and Pharynx	3.4%	Uterus	2.9%
Leukemia	2.6%	Oral Cavity and Pharynx	2.3%
All other sites	32.1%	All other sites	35.3%
<b>Total Cases: 2886800</b>	<b>100%</b>	<b>Total Deaths: 1711000</b>	<b>100%</b>

**Cancer Incidence Rates in Europe (2004)**

Lung 19.5%	27.4% Breast
Prostate 15.5%	13.3% CRC
CRC 12.8%	9.9% Uterus
Stomach 6.7%	6.1% Lung
Oral Cavity and Pharynx 5.0%	5.0% Stomach
Lymphoma 4.2%	4.2% Lymphoma
All other sites 36.3%	34.1% All other sites
<b>Total Cases: 1534700</b>	<b>100%</b>
<b>Total Cases: 1352100</b>	<b>100%</b>

**Cancer Death rates in Europe (2004)**

Lung 27.9%	17.4% Breast
CRC 10.7%	13.4% CRC
Prostate 8.9%	9.8% Lung
Stomach 8.4%	7.6% Stomach
Lymphoma 3.5%	5.0% Uterus
Oral Cavity and Pharynx 3.5%	4.2% Lymphoma
All other sites 37.1%	42.6% All other sites
<b>Total Cases: 962600</b>	<b>100%</b>
<b>Total Cases: 748400</b>	<b>100%</b>

Figure 1. Cancer's classification based on incidence and death rates on the European population in 2004. Adapted from ref. #1.

In the US, the statistics from 2005<sup>2</sup> were similar to those of the European but with some noteworthy differences (Figure 2). In men, prostate, lung, and CRC were, as in Europe, the three cancer types with the highest number of new cases but while lung and CRC percentages were smaller (13.1% to 19.5% and 10.1% to 12.8%, respectively), the percentage of prostate cancer was the double (32.7% to 15.5%). In women, breast and CRC cancers have similar incidence percentages to the European ones (31.9% to 27.4% and 11.1% to 13.3%, respectively) but lung occurrence is higher (12% to 6.1%). The highest mortality accounts for lung (26.6%), breast (14.7%), and CRC (9.4%), like in Europe, but the deaths due to lung cancer are almost three times more frequent in the female population of US than in the European one.

**Cancer Incidence and Death Rates in US (2005)**

Incidence		Death	
Prostate	16.9%	Lung	28.7%
Breast	15.4%	CRC	9.6%
Lung	12.6%	Breast	7.1%
CRC	10.6%	Pancreas	5.6%
Urinary Bladder	4.6%	Prostate	5.3%
Melanoma of Skin	4.3%	Leukemia	3.9%
Non-Hodgkin Lymphoma	4.1%	Non-Hodgkin Lymphoma	3.4%
Uterine Corpus	3.0%	Ovary	2.8%
Pancreas	2.3%	Esophagus	1.9%
All other sites	26.2%	All other sites	31.7%
<b>Total Cases: 1372910</b>	<b>100%</b>	<b>Total Deaths: 570280</b>	<b>100%</b>

Figure 2. Cancer's classification based on incidence and death rates on the US population in 2005. Adapted from ref. #2

Interesting information can be extracted from these data. The first striking fact refers to the huge increase of prostate cancer incidence and death rates in the US male population compared to Europe. The second remarkable observation is the enormous increase of the incidence and death rates of lung cancer among US female inhabitants compared to women in Europe. This may be due to

the smoking habits of American women since it has been shown that smoking is the principle and most important risk factor for lung cancer. The third important piece of information points out CRC as the second cause of death by malignant tumors in both Europe and the US. It affects men and women at the same rate (different from lung cancer, for example, that affects many more male than female subjects). Since more than two thirds of the new cases of CRC appear in developed countries, it is believed that this pathology is strongly influenced by social and geographic components. This is one of the reasons why research in the colorectal cancer field is conducted by many laboratories in the world.

### **3.2. Colorectal Cancer (CRC)**

To better understand what is and how CRC arises it is important to have a notion about the physiology and the histology of the intestinal tract (see 3.2.1.). It is also mandatory to have a brief introduction to the intestinal cell renewal mechanism because its (de)regulation is closely linked to cancer onset.

Around 200 cells per crypt (details in 3.2.1.1.) are generated every day in the intestine. This complicated and precise mechanism needs to be strictly controlled to preserve a correct equilibrium. This equilibrium is called homeostasis and it is maintained by, at least, three different coordinated processes: cell proliferation<sup>3</sup>, cell migration<sup>4</sup>, and anoikis.

The intestinal cell proliferation is not individually driven by each cell type but controlled by the crypt niche, meaning that the two clearly defined proliferative and differentiated compartments are strictly preserved while the cells travel beside the crypt-villi axes<sup>5</sup>. While the location of four to six stem cells<sup>6, 7</sup> at the crypt bottom in the large intestine seems to be clear, their position in the small intestine is less obvious; they have been placed immediately above the Paneth cells<sup>8, 9</sup> or mixed with Paneth cells at the very bottom of the crypts<sup>10-13</sup>. The intestinal stem cells are characterized by preservation of an undifferentiated phenotype, permanent production of all different cell lineages, self-maintenance and renewal abilities, and regeneration capability after damage.

The epithelium layer is subjected to a constant cell migration towards the villi or the surface epithelium. There are only two cell types that escape this effect; Paneth cells and stem cells.

Finally, the processes called anoikis is the cell shedding at the top of the villi, in the small intestine, or at the surface of the epithelium, in the large intestine, by which the cells lose contact with the cellular matrix and undergo apoptosis.

#### **3.2.1. Biology of the gastrointestinal (GI) tract<sup>14-16</sup>**

The gastrointestinal tract, also called the digestive tract or gut, is a group of organs that by a procedure called digestion disrupts and processes the food to get energy and nutrients, discarding the remaining waste. In a normal human adult it is approximately 7.5 meters long.

### 3.2.1.1. Anatomy

The GI tract is composed of two main parts; the upper and the lower gastrointestinal tract, separated, at the same time, in different segments (Figure 3).

The **upper GI tract** encloses the mouth, the esophagus and the stomach.

The **mouth** is the cavity lying at the upper end of the alimentary canal, bounded on the outside by the lips and inside by the oropharynx and containing in higher vertebrates the tongue, gums, and teeth. It is the body opening through which an animal takes in food and water.

The human **esophagus** is about 25 cm long and 2.5 cm in diameter. It is the portion of the digestive tube that conducts food from the pharynx to the stomach. When food is swallowed it passes from the pharynx into the esophagus, initiating rhythmic contractions (peristalsis) of the esophageal wall, which propel the food along toward the stomach. The walls of the esophagus are lined with mucous glands that continue the lubrication of the food as it is conducted to the stomach. The **cardia**, or cardiac sphincter, is the anatomical term for the junction orifice of the stomach and the esophagus. At the cardia, the mucosa of the esophagus transitions into gastric mucosa.

The **stomach** is a saclike dilation in the gastrointestinal tract between the esophagus and the intestines, forming an organ of digestion. The human stomach is a muscular, elastic, pear-shaped bag, lying crosswise in the abdominal cavity beneath the diaphragm. It is capable of gross alterations in size and shape, depending on the position of the body and the amount of food inside. The stomach is about 30.5 cm long and is 15.2 cm wide at its widest point. Its capacity is about 0.94 liters in the adult. Food enters the stomach from the esophagus, through the cardiac sphincter that normally prevents food from passing back to the esophagus. The other end of the stomach empties into the first section of the small intestine, or duodenum; the pyloric sphincter, which separates the two, remains closed until the food in the stomach has been modified and is in suitable condition to pass into the small intestine. The muscular action of the stomach and the digestive action of the gastric juice convert food in the stomach into a semiliquid state called chyme. The stomach is involved in the second phase of digestion, following mastication. Its primary function is to break down large molecules (such as from food) into smaller ones using hydrochloric acid so that they can be absorbed by the small intestine. Secondary functions include temporary storage of food, control of the rate at which food enters the duodenum, acid secretion and antibacterial action, fluidization of stomach contents, protein digestion using pepsin enzymes, and absorbing water, some ions, and some lipid soluble compounds such as alcohol, aspirin, and caffeine. The stomach's interior can secrete 2 to 3 liters of gastric fluid per day.

The **lower GI tract**, also called bowel or intestine, is the muscular hoselike portion of the gastrointestinal tract extending from the lower end of the stomach (pylorus) to the anal opening and, in

Figure 3. The human gastrointestinal tract.

humans and other mammals, consists of two segments, the small intestine and the large intestine or colon. The large intestine is wider in diameter than the small intestine and its direction as it leaves the cecum is upward (ascending colon), across the abdominal cavity (transverse colon) beneath the stomach, and then downward (descending colon) on the left side of the abdominal cavity, making a

Figure 4. The gastrointestinal flora.

a sharp turn in the left lower portion (sigmoid colon) to merge with the rectum. Bacteria, the indigestible residue of food, and mucus form the bulk of matter in the large intestine. The water content of the bulk is absorbed through the walls of the large intestine, and the solid matter is excreted through the rectum. The intestines host several kinds of bacteria that deal with molecules which the human body is not able to breakdown itself (Figure 4).

The **small intestine** is the part of the gastrointestinal tract between the stomach and the large intestine. In humans it is about 5-6 m long and 2.5 cm wide. It joins the large intestine (colon) at the cecum in the right lower abdominal cavity. It is divided in three parts; duodenum, jejunum, and ileum. It is covered in wrinkles which are called plicae circulara. From the plicae circulara project microscopic finger-like pieces of tissue called villi. The purpose of these wrinkles and projections is to increase surface area for absorption of nutrients. Furthermore, each villus is covered in microvilli, which again increase the surface area manyfold. In this region, as well, there is the appendix, a blind pouch, of about 7.5 cm long and less than 1.3 cm wide, projecting from the cecum with no digestive function (it is considered to be a remnant of a portion of the digestive tract which was once more functional and is now in the process of evolutionary regression).

The **duodenum** is the first and shortest (23–28 cm) segment of the small intestine. It begins with the duodenal bulb and ends at the ligament of Treitz. It curves down and then up from the pylorus of the stomach, where chyme (the thick semifluid mass of partly digested food and secretions, formed in the stomach and intestines during digestion) enters it. Ducts from the pancreas and gallbladder bring in bicarbonate to neutralize stomach acid, pancreatic enzymes to further digestion, and bile salts to break up fats. Nutrient absorption begins in the lower duodenum, which has a mucous lining. Exposure to stomach acid makes the upper duodenum susceptible to peptic ulcers, the duodenum's most common problem.

Following the duodenum there is the **jejunum**, the central part of the small intestine. In adults it is 1-2 m long and it has a great mobility, like the ileum, thanks to being suspended by the mesentery, a double layer of peritoneum. The inner surface of the jejunum, its mucous membrane, is covered in projections called villi. It differs from the duodenum due to lack of Brunner's glands. It is also different from the ileum due to fewer goblet cells and generally lacks Peyer's patches.

The **ileum** is the final and longest (about 2-4 m) segment of the small intestine. It extends from the jejunum to the ileocecal valve, where it joins the cecum. Its function is to absorb vitamin B12

and bile salts. The wall itself is made up of folds, with many villi on its surface. Moreover, the epithelial cells which line these villi possess even larger numbers of microvilli. As a result, the ileum has an extremely large surface area both for the adsorption of enzyme molecules and for the absorption of products of digestion. The cells that line the ileum contain the protease and carbohydrase enzymes responsible for the final stages of protein and carbohydrate digestion. These enzymes are present in the cytoplasm of the epithelial cells. The villi contain large numbers of capillaries which take the amino acids and glucose produced by digestion to the hepatic portal vein and the liver. A difference between the ileum and the other regions of the small intestine is its lymphoid tissues. While the length of the intestinal tract contains lymphoid tissue, only the ileum has abundant Peyer's patches, unencapsulated lymphoid nodules containing large amounts of lymphocytes and other cells of the immune system.

The small intestine has different functions; it is not only an organ of digestion (for that part of the process not completed by the stomach) but is the chief organ of absorption; it is the site where most of the nutrients from ingested food are absorbed. By contraction of its muscular walls (peristalsis) the food mass is propelled onward and, as it is carried along, it is subject to the digestive action of the secretions of the intestinal lining as well as to that of bile and pancreatic juice which enter the upper intestine (duodenum) from ducts leading from the liver and pancreas. The digestion of proteins into peptides and amino acids principally occurs in the stomach but some also occurs in the small intestine. The small intestine is where the majority of chemical digestion takes place; peptides are degraded into amino acids; lipids (fats) are degraded into fatty acids and glycerol; and carbohydrates are degraded into simple sugars (e.g., glucose).

There are many diseases affecting the small intestine. Here, I will just briefly mention two of them: Crohn's Disease and small intestine cancer.

Cancer of the small intestine is relatively rare compared to colorectal cancer<sup>17</sup>. It can be subdivided into duodenal cancer, and cancer of the jejunum and ileum. The different subtypes of small intestine cancer include adenocarcinomas, gastrointestinal stromal tumor, lymphoma, and carcinoid.

Crohn's disease (CD) is a chronic, episodic disease which can affect any part of the gastrointestinal tract from mouth to anus. Because it is a systemic disease, it can also cause complications outside of the gastrointestinal tract<sup>18</sup>. The main gastrointestinal symptoms are abdominal pain and diarrhea, which may be bloody. Symptoms outside the gastrointestinal tract include skin rashes, arthritis, and ulcers in the mouth. CD is a type of inflammatory bowel disease (IBD). IBD occurs when the immune system contributes to damage of the gastrointestinal tract by causing inflammation. Crohn's disease can be difficult to distinguish from other forms of IBD such as ulcerative colitis. Because of the name, IBD can be confused with irritable bowel syndrome (IBS), a less serious condition. CD affects between 400000 and 600000 people in North America<sup>19</sup>. Prevalence estimates for Northern Europe have ranged from 27–48/100000<sup>20</sup>. Although the cause of Crohn's disease is not known, it is widely believed to be an autoimmune disease. There is a genetic component to susceptibility, and the disease may be triggered in a susceptible person by environmental factors. Unlike the other major type of IBD, ulcerative colitis, there is no known medical

or surgical cure for Crohn's disease. Many medical treatments are however available for Crohn's disease with a goal of keeping the disease in remission<sup>21</sup>.

The **large intestine** is the other segment of the lower GI tract. It extends from the end of the ileum to the anus. It is divided into the cecum, the colon, the rectum and the anus. The large intestine is longer in herbivores and shorter in carnivores, and is about 1.2 to 1.8 m long in humans. Its caliber, greater than that of the small intestine, is largest at its commencement at the cecum, and gradually diminishes as far as the rectum, where there is a dilation of considerable size just above the anal canal.

The first part of the large intestine is the **cecum**. It is a pouch of about 7.5 to 8.5 cm in diameter connected to the ascending colon and the ileum. It is separated from the ileum by the ileocecal valve (ICV) or Bauhin's valve, and is considered to be the beginning of the large intestine.

Nearby the cecum, there is a blind-ended tube called the *appendix*. It develops embryologically from the cecum. It averages 10 cm in length, but can range from 2-20 cm. The diameter of the appendix is usually less than 7-8 mm. While the base of the appendix is at a fairly constant location, the location of the tip of the appendix can vary from being retrocaecal to being in the pelvis to being extraperitoneal. In most people, the appendix is located at the lower right quadrant of the abdomen. Currently, the function of the appendix, if any, remains controversial in the field of human physiology. One explanation has been that the appendix is a remnant of an earlier function, with no current purpose.

The **colon** is the part of the intestine located between the cecum and the rectum. It consists of different segments; the ascending colon, the transverse colon, the descending colon and the sigmoid colon, that joins the rectum. The colon from cecum to the mid transverse colon is also known as the right colon. The remainder is known as the left colon.

The first part of the colon is known as the *ascending colon*. The ascending colon expands from the cecum to the hepatic flexure (the turn of the colon by the liver).

Following the hepatic flexure comes the *transverse colon* extending till the splenic flexure (the turn of the colon by the spleen). The transverse colon hangs off the stomach, attached to it by a wide band of tissue called the greater omentum. On the posterior side, the transverse colon is connected to the posterior abdominal wall by a mesentery known as the transverse mesocolon. The transverse colon is encased in peritoneum, and is therefore mobile (unlike the parts of the colon immediately before and after it).

The *descending colon* is the part of the colon from the splenic flexure to the beginning of the sigmoid colon. It is retroperitoneal in two-thirds of humans. In the other third, it has a (usually short) mesentery.

The *sigmoid colon* is the last part of the large intestine before the rectum. Its diameter is approximately 2.5 cm, being the narrowest portion of the colon. The walls of the sigmoid colon are muscular, and contract to increase the pressure inside the colon, causing the stool to move into the rectum.

Next to the sigmoid colon appears the **rectum**, the final straight portion of the intestine, of about 12 to 15 cm in length, which ends in the **anus**. The anus is the external opening of the rectum

and is approximately 4 cm long. Closure is controlled by sphincter muscles. Feces are expelled from the body through the anus during the act of defecation, which is its primary function.

The colon has different functions; to lubricate waste products, to absorb remaining fluids (added to the food during digestion), salts and vitamins, and to store waste products until excretion. It has no digestive function (no digestive enzymes are secreted). By the time the chyme has reached the colon, almost all nutrients and 90% of the water have been absorbed by the body in the small intestine. At this point some electrolytes like sodium, magnesium, and chloride are left as well as indigestible carbohydrates known as dietary fiber. As the chyme moves through the large intestine, most of the remaining water is removed, while the chyme is mixed with mucus and bacteria known as gut flora, and becomes feces.

Figure 5. **Functions of the intestinal flora.** (A) Bacteria density increases in the jejunum/ileum from the stomach and duodenum, and in the large intestine, colon-residing bacteria achieve the highest cell densities recorded for any ecosystem. The most common anaerobic and aerobic genera are listed. (B) Commensal bacteria exert a miscellany of protective, structural and metabolic effects on the intestinal mucosa. Adapted from reference #22.

The bacteria break down some of the fiber for their own nourishment and create acetate, propionate, and butyrate as waste products, which in turn are used by the cell lining of the colon for nourishment. A part of these and other metabolic functions, the gut flora also plays important protective and structural roles<sup>22</sup> (Figure 5).

The colon is affected by several diseases such as Crohn's disease (mentioned above) and cancer (see 3.2.), among many others.

### 3.2.1.2. Histology

The GI tract has a uniform general histology with some differences which reflect the specialization in functional anatomy. The GI tract can be divided into 4 concentric layers surrounding the inner cavity, the lumen: mucosa, submucosa, muscularis propria (or m. externa), and serosa (Figure 6).

Figure 6. Histology of the gastrointestinal tract. Adapted from ref. #15.

The **mucosa** is the innermost layer of the GI tract, surrounding the lumen, or space within the tube. This layer comes in direct contact with the food (or bolus), and is responsible for absorption and secretion, important processes in digestion. The mucosa are highly specialized in each organ of the GI tract, facing a low pH in the stomach, absorbing a multitude of different substances in the small intestine, and also absorbing specific quantities of water in the large intestine. Reflecting the varying needs of these organs, the structure of the mucosa can consist of invaginations of secretory glands, like the gastric pits, or it can be folded in order to increase surface area, for instance villi and microvilli (only present in the small intestine) (Figure 7).

The intestinal villi, fingerlike projections that protrude into the intestinal lumen, are approx. 0.5-1.5 mm long and cover the mucosal surface. The microvilli, sub-light microscopic tubular projections, are extensions of the apical cell membrane and compose the brush border. This complex membranous network contains the enzymes, receptors, and carriers required for terminal digestion and absorption. It can be divided into epithelium, lamina propria (connective tissue core), and muscularis mucosae (layers of smooth muscle).

Figure 7. Morphology of the intestinal and the colonic mucosa of an adult mouse. The small intestine epithelium is organized into crypts and villi (delimited by dashed lines). In the colon, the crypts are larger, and there are no villi but a flat surface epithelium. The villus and surface epithelium of the colon consist of differentiated epithelial cells, while the crypts are proliferative units as shown by expression of the cell cycle marker KI-67 (arrows). Adapted from reference #40.

The intestines contain a complex, rapidly proliferating, and perpetually differentiating **epithelium**. The epithelium constitutes the major barrier between the intestinal lumen and the lamina propria and regulates fluxes between these two compartments. Epithelial cell migration and differentiation occurs continuously, and the process of cellular renewal takes approximately three to five days. Cellular differentiation starts during migration to the upper part of the crypt (Lieberkühn crypts) and to the villi base. Microvilli become more prominent, and the cell's capacity to absorb lipids, sugars, and amino acids increases. Shedding cells are removed from the top of the villi (in the small intestine) and the crypts (in the large intestine) by a process known as *anoikis*, in which altered cellular adhesion results in apoptosis (Figure 8).

**Figure 8. (A) The structure of the adult small intestine.** Putative stem cells reside immediately above the Paneth cells. Base columnar cells, intermingled between the Paneth cells, may also behave as stem cells. Progenitors stop proliferating at the crypt-villus junction and express differentiation markers. Enteroendocrine, absorptive, and mucosecreting cells migrate upward, whereas Paneth cells migrate downward and localize at the bottom of the crypts. **(B) Structure of the large intestine.** Stem cells reside at the crypt bottom. Progenitors are amplified by constant division along the bottom two thirds of the crypts. Paneth cells are absent in the large intestine. Cell cycle arrest and differentiation occur when progenitors reach the top third of the crypts. Adapted from reference #26.

The epithelial cells are replaced by replication of the descendants of epithelial stem cells, believed to reside in the lower crypt region, approximately four to five cell positions above the crypt base (small intestine) or at the bottom of the crypt (large intestine). The anchored stem cells are the source of the four principal differentiated epithelial cell types in the adult intestinal epithelium<sup>23, 24</sup>; the enterocytes (absorptive cells), the goblet cells, the endocrine cells, and the Paneth cells (Figure 9).

The cells that are fated to become the *enterocytes* or *absorptive cells*, the most abundant of the epithelial cells, begin to express a variety of specific genes which enable these cells to digest and absorb many different nutrients.

The role of *goblet cells* is to secrete mucus, a viscous fluid composed primarily of highly glycosylated proteins called mucins suspended in a solution of electrolytes. Mucus serves many functions, including protection against shear stress and chemical damage. They are present throughout the entire GI tract but they are more numerous in the ileum than in the jejunum. These cells exhibit a brandy-goblet shape and are characterized by apically located granules filled with mucins.

The intestine contains remarkably complex types of *endocrine cells*. Although they all arise from a common stem cell, there may be a branch point at which proliferating progenitor cells differentiate into the various endocrine cell lineages. The secretion of these cells may have a multitude of effects on the intestines, like motility and intestinal cellular secretion. They exhibit an appreciable basal surface, and their widths narrow superiorly so that only narrow bands of apical cytoplasm reach the lumen. Their secretory granules are located predominantly in the basal cytoplasm below the nucleus, ready to be secreted by exocytosis through the basal membrane into the lamina propria.

**Figure 9. (A) The anatomy of the adult small intestinal epithelium.** The epithelium of the adult small intestine is shaped into crypts and villi. The crypt compartment contains the stem cells, the transit amplifying cells and the Paneth cells, whereas the villus compartment is made up of enterocytes, goblet cells and enteroendocrine cells. The pluripotent stem cells give rise to the transit amplifying cells. These cells divide vigorously before they terminally differentiate into one of the four principle cell types: enterocytes, goblet cells, enteroendocrine cells and Paneth cells. **(B) Chemical and immunohistochemical detection of the four principal cell lineages of the small intestine** (arrowheads): villus-associated absorptive cells (alkaline phosphatase), Goblet mucus-secreting cells (periodic acid/Schiff), enteroendocrine cells (synaptophysin), and Paneth cells (lysozyme) (reproduced from Pinto et al., 2003, with permission). The upper small panels show the entire crypt-villus axis while the lower large panels show magnifications of the crypts. Adapted from references #23&24.

*Paneth cells* are pyramid-shaped cells that reside in the crypt base and contain large eosinophilic secretory granules located in the apical cytoplasm. They are present in the small intestine but not in the colon. Paneth cells provide host defense against microbes in the small intestine. They are functionally similar to neutrophils. When exposed to bacteria or bacterial antigens, Paneth cells secrete a number of antimicrobial molecules into the lumen of the crypt, thereby contributing to maintenance of the gastrointestinal barrier. As said before, small intestinal crypts house stem cells that serve to constantly replenish epithelial cells that die and are lost from the villi. Protection of these stem cells is essential for long-term maintenance of the intestinal epithelium, and the location of Paneth cells adjacent to stem cells suggests that they play a critical role in defending epithelial cell renewal. The principal defense molecules secreted by Paneth cells are alpha-defensins, also known as cryptdin. These peptides have hydrophobic and positively-charged domains that can interact with

phospholipids in cell membranes. This structure allows defensins to insert into membranes, where they interact with one another to form pores that disrupt membrane function, leading to cell lysis. Due to the higher concentration of negatively-charged phospholipids in bacterial than vertebrate cell membranes, defensins preferentially bind to and disrupt bacterial cells, sparing the cells they are functioning to protect. Paneth cells are stimulated to secrete defensins when exposed to bacteria (both Gram positive and negative types) or such bacterial products as lipopolysaccharide, muramyl dipeptide and lipid A. In addition to defensins, Paneth cells secrete lysozyme and phospholipase A2, both of which have clear antimicrobial activity. This battery of secretory molecules gives Paneth cells a potent arsenal against a broad spectrum of agents, including bacteria, fungi and even some enveloped viruses.

The **lamina propria** extends from the simple columnar epithelium to the muscularis mucosae and contains many cells involved in immunologic functions. It forms the connective tissue core of the villus and fills the spaces between glands. Primarily a reticular tissue framework with numerous lymphocytes, eosinophils, and plasma cells. It has abundant plasma cells manufacture most of the antibody proteins.

The **muscularis mucosae** are several thin layers of smooth muscle fibers located outside the lamina propria and adjacent to the submucosa. They are oriented in different ways which keeps the mucosal surface and underlying glands in a constant state of gentle agitation to expel contents of glandular crypts and enhance contact between epithelium and the contents of the lumen. It aids in the action of continued peristalsis along the gut.

The **submucosa** is a loose connective tissue layer containing numerous arteries as well as venous and lymphatic plexuses that support the mucosa, and muscularis mucosae. It also joins the mucosa to the bulk of underlying smooth muscle. Typical connective tissue cells are also present, but vascular structures predominate, consistent with the role of this portion of the gut as a conduit for absorptive and digested products. Tiny parasympathetic ganglia are scattered around forming the submucosal plexus, or "Meissner's plexus", where preganglionic parasympathetic neurons synapse with postganglionic nerve fibers that supply the muscularis mucosae.

The **muscularis propria** (m. externa) consists of a circular inner muscular layer and a longitudinal outer muscular layer condensed into three bands, the teniae coli. The circular muscle layer prevents the food from going backwards and the longitudinal layer shortens the tract. The coordinated contractions of these layers are called peristalsis and propel the bolus, or balled-up food, through the GI tract. Between the two muscle layers are the myenteric muscle or Auerbach's plexa.

The **serosa** is a mesothelial cell layer overlying loose connective tissue coated in mucus to prevent friction damage from the intestine rubbing against other tissues. The mesothelium consists of a single layer of vascular flat nucleated cells (simple squamous epithelium) which produce the lubricating serous fluid. This fluid has a consistency similar to thin mucous. These cells are bound tightly to the underlying connective tissue. The connective tissue layer provides the blood vessels and nerves for the overlying secretory cells, and also serves as the binding layer which allows the whole serous membrane to adhere to organs and other structures.

The four concentric layers mentioned above, surround the interior part of the GI tract, called lumen. The **lumen** is the cavity where digested material passes through and from where nutrients are absorbed. The luminal content of the gut is mostly water and therefore chemically represents an aqueous phase. Depending on the location of the gut, the aqueous phase contains acid (i.e., stomach), digestive enzymes (i.e., mouth, esophagus, stomach, and small intestine), or bacteria (i.e., predominately large intestine).

### 3.2.2. Signaling Pathways involved in CRC

Proliferation, cell fate specification, differentiation, migration, and cell death in the intestinal tract are precise and complex processes that are regulated through highly synchronized and interconnected developmental programs<sup>25, 26</sup>.

The evolutionary conserved Wnt<sup>27, 28</sup>, Notch<sup>29, 30</sup>, TGF-Beta<sup>31, 32</sup>, BMP<sup>33, 34</sup>, Hedgehog<sup>35, 36</sup>, and RAS/RAF<sup>37, 38</sup> signaling pathways have been shown to be key players in the maintenance and control of homeostasis and anoikis of the small and large intestines.

Many sporadic tumors as well as hereditary syndromes arise and progress due to deregulation (i.e., activation or inactivation) of these signaling cascades. This fact points out how essential and crucial is the correct and controlled functionality of these pathways is in distinguishing the thin line that separates the accurate proliferation/differentiation equilibrium from the apparition of tumor pathologies in these tissues.

#### Wnt signaling pathway

The Wnt signaling pathway is highly conserved among all metazoa. Our knowledge about this pathway comes from genetic approaches done in nematode, Drosophila, Xenopus, zebrafish, and mouse<sup>39</sup>, combined with biochemical approaches (Figure 10).

Figure 10. The Wnt signaling pathway.

The Wnt signaling pathway is the physiological regulator of epithelium homeostasis<sup>24, 40, 41</sup>. The canonical Wnt signaling pathway is activated when the secreted Wnt glycoproteins bind to the

complex formed by the frizzled (Fz; seven transmembrane receptors) and LRP5/6 (single transmembrane co-receptors members of the low-density lipoprotein receptor related family) receptors.

There are secreted frizzled-related (SFRPs) proteins that bind to the Wnt ligands and block the interaction with Fz proteins. LRP5/6 can also be blocked by other factors (for example, Dkk-1). When the Wnt ligands can not interact with the Fz and LRP5/6 receptors, APC, together with AXIN2, CK1, GSK3-beta, and others, forms a complex in the cytoplasm. CK1 and GSK3-beta sequentially phosphorylate beta-catenin, the central player of this cascade, which is targeted for degradation by the ubiquitin-proteasome pathway.

When the signaling cascade is activated by the Wnt ligands the destruction complex is not active anymore leading to beta-catenin accumulation. Then, beta-catenin translocates into the nucleus, where it interacts with the DNA-binding proteins of the T cell factor/lymphoid-enhancing factor (TCF/LEF) family to form a transcription complex involved in transcriptional activation of many target genes.

Several sources of evidence suggest that Wnt signaling to be activated in intestinal proliferative cells<sup>42-44</sup>; i) nuclear accumulation of beta-catenin, ii) presence of CRC after mutational activation of the signaling cascade, iii) loss of proliferation after mutation of the TCF/LEF family member TCF4<sup>45</sup>, iv) change of CRC cells phenotype (from a crypt-like phenotype to a differentiated villi epithelial phenotype) after inhibition of beta-catenin/TCF4 activity<sup>46, 47</sup>, and v) reduction of epithelial proliferation and loss of crypts after targeted expression of Wnt inhibitors<sup>48</sup>.

The link between Wnt signaling deregulation and CRC has been largely investigated. It has been shown that mutations in APC gene resemble in upregulation of beta-catenin nuclear and cytoplasmic levels<sup>49, 50</sup>. Mutations in AXIN2 or beta-catenin itself also lead to accumulation of beta-catenin in the nucleus and activation of the bet-catenin/TCF4 transcription complex<sup>41, 51</sup>. Many studies have been done to find out Wnt target genes but the final list is still far from completion<sup>47, 52</sup>.

Many animal models have been created to try to better understand this pathway and its implication in intestinal cancer, the *Min* mouse model (Min: multiple intestinal neoplasia; is a mutant allele of murine *APC* encoding a nonsense mutation in codon 850) being the most commonly used. Another mutation, the *APC*<sup>Δ716</sup>, gives a truncated protein of 716 amino acids. Heterozygous mice for the *Min* or the *APC*<sup>Δ716</sup> mutations get dozens of adenomas<sup>53-55</sup>.

### Notch signaling pathway

Intestinal homeostasis is under the control of various developmental signaling pathways one of which is the Notch signaling pathway. Many cell fate decisions and differentiation processes are regulated by *Notch* genes.

*Notch* genes are single transmembrane receptors conserved through evolution. There are four different Notch receptors (NOTCH1/2/3/4) and five

Figure 11. The Notch signaling pathway. Adapted from reference # 23.

ligands (DLL1/3/4; JAG1/2)<sup>56</sup>. When receptors are activated by transmembrane ligands of neighboring cells<sup>29</sup>, a cascade of proteolytic cleavages of the receptor close to and within the transmembrane domain starts. This leads to the release and translocation of the Notch intracellular domain (NICD) into the nucleus where the transcription factor CSL (CBF1/RBPjk) engages and activates transcription<sup>56, 57</sup> (Figure 11).

Lack of Notch signaling makes CSL to function as a transcriptional repressor. In clusters of precursor cells, Notch controls cell fate choices between adjacent cells. The signal cascade is triggered when a cell reaches higher levels of ligands than the surrounding neighboring cells. There are many known Notch target genes but some of the best characterized ones are members of the hair/enhancer of split (HES) family of transcriptional repressors, which are nuclear basic helix-loop-helix (bHLH) proteins. In turn, these HES proteins regulate downstream genes<sup>58, 59</sup>.

Much work has been done with animal models to understand the Notch signaling and its implications in intestinal cell fate<sup>60-68</sup>.

### TGF-Beta signaling pathway

Many important biological processes, such as angiogenesis, cell differentiation and proliferation, wound healing, and embryonic development, are controlled and regulated by the TGF-beta signaling pathway<sup>32, 69, 70</sup>.

The family of TGF-beta cytokines is vast and includes the TGF-beta family members, bone morphogenic proteins (BMPs), and activins. The two surface serine-threonine kinase receptors (type I and type II) are brought together by the ligands and this leads to the phosphorylation of the first receptor by the second. There are three different classes of SMAD proteins, which are the intracellular

Figure 12. The TGF-beta signaling pathway. Adapted from reference #70.

messengers of this pathway: receptor-regulated SMADs (R-SMADs: SMAD1/2/3/5/8), common SMAD (co-SMAD: SMAD4), and inhibitory SMADs (I-SMADS: SMAD6/7). The association between activated type I receptors and SMAD4 cause R-SMADs phosphorylation and translocation into the nucleus (Figure 12). There, transcription of target genes is regulated by the interaction between the SMAD complex with coactivators or corepressors of transcription. SMAD2/3 are the primary mediators in TGF-beta signaling whereas SMAD1/5/8 mediate BMP signaling.

TGF-beta signaling has been shown to be altered in CRC, concretely at the adenoma/carcinoma transition<sup>71</sup>. The inactivation of the TGF-beta receptor type II (TGFR2) is the most frequent mutation and affects either microsatellite stable (MMS) and unstable (MMI) tumors<sup>72</sup>, although SMAD2 and SMAD4 are also mutated in CRC<sup>73, 74</sup>. A number of animal models have been

created to investigate the function of TGF-beta signaling in development and disease. Inactivating mutations for TGFB1/2/3, TGFB2, SMAD2, SMAD3, and SMAD4 have been reported<sup>75, 76</sup>. Interestingly, in a SMAD4 deficient homozygosity, benign adenomas in APC<sup>Δ716</sup> mice progressed to carcinomas very quickly<sup>77</sup>. Based on the results obtained in animal models, the absence of TGF-beta signaling more than to initiate tumorigenesis, accelerates the development of already existent early tumors.

### BMP signaling pathway

As well as the above mentioned TGF-beta signaling pathway, BMP modifies target gene transcription by receptor-mediated intracellular signaling<sup>34</sup> (Figure 13).

There are two types of BMP receptors; type I (BMPRI1A and BMPRI1B) and type II (BMPRI2). In the canonical BMP pathway, BMP receptors type I activate SMAD1/5/8 by phosphorylation<sup>78</sup>. A dimer of phosphorylated R-SMADs then forms a complex with SMAD4. This heterodimeric complex

Figure 13. The BMP signal transduction pathway. Adapted from reference #34.

translocates into the nucleus and binds to transcription factors regulating the expression of target genes<sup>31, 69</sup>. A non-canonical BMP pathway is driven by TGFh1 activated tyrosine kinase 1 (TAK1, a MAPKKK) and through mitogen activated protein kinase (MAPK)<sup>31, 79</sup>. In addition, X-linked inhibitor of apoptosis (XIAP) links the BMP receptor signal to TAK1, and TAK1 binding proteins (TAB1/2/3) are also required for BMP-mediated TAK1 activation<sup>80, 81</sup>. TAK1 can also trigger Jun N-terminal kinase (JNK) and NF-kB<sup>82</sup>.

In the canonical BMP pathway, SMAD function can be inhibited through blocking its translocation to the nucleus by Erk, in response to GF/CK signaling through Ras/Raf/Mek<sup>83</sup>. Germline mutations affecting SMAD4 or BMPRI1A are associated to 50% of Juvenile Polyposis Syndrome (JPS)<sup>84-86</sup>.

In this case animal models also help to understand the mechanism of this pathway and its role in JPS<sup>87</sup>.

### Hedgehog signaling pathway

Hedgehog ligands control cell fate specification during development.

The 12-transmembrane protein called Patched (PTCH) is the receptor for secreted Hedgehog proteins (HH). In the absence of ligand, PTCH inhibits Smoothened (SMO), a 7-transmembrane protein, blocking the signaling cascade<sup>88</sup>. When HH binds to PTCH<sup>89</sup> releases SMO inhibition, leading to activation of the GLI family of Zn-finger transcription factors (GLI1/2/3)<sup>90</sup> (Figure 14). Activated GLI accumulates in the nucleus<sup>91</sup> and controls the transcription of Hedgehog target genes<sup>92-94</sup>.

Mutations in the Hedgehog pathway are associated with multiple malformations along the GI tract<sup>95-97</sup>. The development of sporadic tumors of the skin, cerebellum, and skeletal muscle are related to activating mutations of the Hedgehog signaling pathway<sup>98, 99</sup>.

Figure 14. The Hedgehog signaling pathway. Adapted from reference #88.

The autocrine/paracrine activation of the Hedgehog pathway in the esophagus, stomach, biliary tract, or pancreas (all of them members of the upper GI tract) seems to be critical for tumor growth<sup>100, 101</sup>.

### RAS/RAF signaling pathway

The activation of the RAS/RAF/MAPK cascade supports cell proliferation and cell differentiation. RAS genes are GDP/GTP-regulated binary switches.

The formation of the active GTP-bound form of RAS and its conversion to the inactive GDP-bound state is mediated by guanine exchange factors (GEFs) and GTPase activating proteins (GAPs), respectively. Active GTP-bound RAS interacts with RAF (RAF1, A-RAF, or B-RAF) to form a high-affinity complex. As a result of this interaction, RAF gets activated (Figure 15). Then a number of consecutive phosphorylation events take place; RAF phosphorylates MEKs (MEK1/2), which sequentially activates MAPKs (p42 and p44, also called extracellular regulated kinases; ERKs) by phosphorylation. Once phosphorylated, MAPKs translocate into the nucleus to phosphorylate a number of transcription factors, triggering gene expression.

Many mutations in K-RAS and B-RAF have been associated with CRC. Around 50% of CRC carry an activating mutation in K-RAS<sup>102, 103</sup>. Complementation between K-RAS and B-RAF mutations has been described (20% of the CRC with no K-RAS mutation have B-RAF activated<sup>104, 105</sup>) and suggests a key role for the RAS/RAF/MAPK cascade in colorectal tumorigenesis. Interestingly, K-RAS mutations are more frequent in MMR-proficient tumors, whereas B-RAF mutations occur mostly in MMR-deficient lesions<sup>105</sup>.

Mutations in K-RAS and B-RAF seem to be related more to cancer progression than to cancer initialization because they are not present in small adenomas<sup>102, 105</sup>. The function of the

RAS/RAF/MAPK pathway in cell renewal of the intestinal epithelium seems to be related to transduction of signals from the membrane to the nucleus.

Work with animal models has not elucidated a key role for K-RAS in the initial stages of cancer in the intestine<sup>106-110</sup>.

Figure 15. The RAS/RAF signaling pathway.

After this overview of the pathways that control and regulate physiologic homeostasis of the intestines, there are evidences that show that cancer cells have developed abilities to mutate key genes on these pathways to assure cancer progression. Furthermore, crosstalk mechanisms between them facilitate their activation through different ways, making more difficult the finding of drugs that could effectively block their signaling cascades to prevent cancer formation.

### 3.2.3. DNA repair mechanisms, Mismatch Repair (MMR), and MMR defects and Cancer

The processes by which damage present in DNA molecules is detected and eliminated are known as DNA repair mechanisms. Every day, a cell must deal with a continuous onslaught of DNA lesions. This damage can come from environmental or endogenous sources. Both DNA damage sources result in between  $1 \times 10^3$  and  $1 \times 10^6$  individual molecular lesions per cell per day<sup>111</sup>.

The vast majority of DNA damage implies a chemical modification of the bases, the primary structure of the double helix. A failure in repairing these kinds of lesions can trigger a harmful mutation rate, genomic instability, or cell death. Damage in DNA repair genes or in genes responsible of cell cycle regulation can lead to aggressive and invasive diseases (e.g., cancer). DNA damage during replication before cell division can provoke base misincorporation and therefore unrecoverable inheritance of mutations by the daughter cells (unless gene conversion, a rare case of back mutation, occurs).

DNA repair rate depends on many factors, including cell type, age of the cell, and extracellular environment. Those cells carrying large amounts of DNA damage, or those in which the DNA repair system is not able to repair the incoming DNA damage, can follow three different processes: i)

senescence (or irreversible state of dormancy), ii) apoptosis (or programmed cell death), or iii) cancer (i.e., deregulated cell division and proliferation).

As said, there are two different sources of DNA damage; endogenous DNA damage (i.e., damage generated by the byproducts of cellular metabolism: oxidation of bases and generation of strand interruptions by reactive oxygen species, alkylation of bases by endogenous alkylating agents, hydrolysis of bases such as deamination, depurination and depyrimidation, and DNA single- and double-strand breaks resulting from collapsed DNA replication forks or from oxidative destruction of deoxyribose residues<sup>112, 113</sup>), and exogenous DNA damage (such as chemical agents, UV radiation, and ionizing radiation).

Depending on the type of damage done to the DNA's double helical structure, a variety of repair strategies have evolved to restore lost information<sup>114</sup>. If possible, cells use the unmodified complementary strand of the DNA or the sister chromatid as a template to losslessly recover the original information. Without access to a template, cells use an error-prone recovery mechanism known as translesion synthesis as a last resort.

Some types of DNA damage are so common that they have their own cellular subsystem dedicated to counteracting them. These mechanisms do not require a template, since the types of damage they counteract can only occur in one of the four bases. Such direct reversal mechanisms are specific to the type of damage incurred.

The damage can affect only one or both strands of the double helix. When damage consists on a break in both strands there are two mechanisms to repair it; non-homologous end-joining (NHEJ), and homologous recombination (HR) repair<sup>114, 115</sup>. When only one of the two strands carries a defect, the other strand is used as a template for repairing. The mechanisms that do this kind of repair are base excision repair (BER), nucleotide excision repair (NER), and mismatch repair (MMR)<sup>114, 115</sup>. Because our institute is mainly focused on the study of the MMR system, I will explain in more detail how this mechanism works in prokaryotic and eukaryotic organisms.

### 3.2.3.1. *E.coli* and eukaryotic MMR mechanisms

The major function of the postreplicative MMR system is to eliminate biosynthetic errors (base-base mismatches and short insertion/deletion loops, IDLs) from newly synthesized DNA. If not repaired, these errors will lead to base-substitutions and frameshift mutations.

The term "postreplicative" implicates MMR in the correction of errors coming from DNA replication. This is due to the fact that the fidelity of polymerases implicated in DNA replication is high (incorrect nucleotide incorporation rate around  $1 \times 10^{-4}$ - $1 \times 10^{-6}$  before intrinsic exonucleolytic proofreading activity and  $1 \times 10^{-7}$ - $1 \times 10^{-8}$  after it<sup>116</sup>) but not enough to produce a copy of the entire genomic DNA without errors. MMR ensures error free duplication of the human genome by reducing the error rate to  $1 \times 10^{-9}$ - $1 \times 10^{-10}$ .

Even though great advances in the biochemical and structural aspects of MMR have been achieved in the last years, the precise biological functions of the key players of the human MMR system have not yet been elucidated.

MMR proteins are divided in two categories; MutS homologues (MSH: hMSH2, hMSH3, and hMSH6), and MutL homologues (MLH: hMLH1 and hPMS2, where PMS stands for Post Miotic Segregation). Other MLH/PMS homologues are also known (hMSH4, hMSH5, hPMS1, and hMLH3) but their roles are largely uncharacterized. MutS and MutL homologues need to form complexes to be functional (Table 1). MMR proteins, DNA replication factors (replication protein A (RPA), proliferating cell nuclear antigen (PCNA), replication factor C (RFC), DNA polymerase delta: Pol $\delta$ ), and exonucleolytic enzymes (exonuclease-1: EXO1) functionally interact in the human MMR machinery.

Table 1. **Human MutS and MutL homologue complexes that are involved in mismatch repair.** Adapted from reference #117.

Complex	Components	Function
MutS $\alpha$	MSH2, MSH6	Recognition of base–base mismatches and small IDLs
MutS $\beta$	MSH2, MSH3	Recognition of IDLs
MutL $\alpha$	MLH1, PMS2	Forms a ternary complex with mismatch DNA and MutS $\alpha$ ; increases discrimination between heteroduplexes and homoduplexes; also functions in meiotic recombination
MutL $\beta$	MLH1, PMS1	Unknown
MutL $\gamma$	MLH1, MLH3	Primary function in meiotic recombination; backup for MutL $\alpha$ in the repair of base–base mismatches and small IDLs

IDL, insertion/deletion loop; MLH, MutL homologue; MSH, MutS homologue; PMS, post-meiotic segregation protein.

The MMR is a highly conserved system from bacteria to human. Such a level of evolutionary conservation is due to its pivotal role in the maintenance of genomic stability. For this reason, much of our understanding of mammalian MMR came from studies done on *E.coli* and *S.cerevisiae* (revised in <sup>117-119</sup>).

### MMR in *E.coli*

There are two most important conditions the MMR system has to fulfill; efficient recognition of base-base mismatches and IDLs, and application of the repair machinery to the newly synthesized DNA strand, where the error has been incorporated. How these two criteria are accomplished has been revealed in *in vitro* studies using the *mutS*, *mutL*, *mutH*, and *uvrD* *E.coli* mutated strains<sup>120</sup>.

When a mismatch occurs, a MutS homodimer, via ATP hydrolysis, recruits a homodimer of MutL to activate MutH, which then binds to a hemi-methylated GATC site (it is normally methylated on adenine, but transiently unmethylated because deoxyadenine methylase lags behind the replication fork by approximately 2 minutes) (Figure 16A).

Once the unmethylated strand has been cleaved by the MutS/MutL-dependent activated form of MutH, the unwinding of the ends of the error-containing strand from the template by UvrD helicase allows one of the 5'-3' (RecJ or ExoVII) or 3'-5' (ExoI, ExoVII or ExoX) exonucleases, depending on where the nearest hemi-methylated GATC site lies from the mismatch, to degrade the unwound DNA.

After the mismatch has been removed, the resynthesis is mediated by DNA polymerase III and DNA ligase.

### Eukaryotic MMR mechanism

Even though the MMR system is conserved, the mechanism in eukaryotes is more complex than in *E.coli*. Five human MutS homologues (hMSH2, hMSH3, hMSH4, hMSH5, and hMSH6) have

been identified although only hMSH2, hMSH3, and hMSH6 take part in MMR (hMSH4, and hMSH5 are exclusively involved in meiotic recombination).

**Figure 16. Postreplicative mismatch repair.** **a** | In *Escherichia coli*, newly synthesized DNA (green) is transiently unmethylated at GATC sites (empty circles). The mismatch (red triangle)-activated MutS–MutL–ATP complex licenses the MutH endonuclease to incise the nearest unmethylated GATC sequence (either 5' or 3' from the mismatch). UvrD helicase, together with one of several exonucleases (Exo), generate a gap that extends from the nick to ~100 nucleotides past the mismatch, and which is stabilized by the single-stranded DNA-binding protein Ssb. This gap is filled (shown in red) by DNA polymerase III (pol III) and the remaining nick is sealed by DNA ligase. The GATC sites are then methylated (solid blue circles) by deoxyadenine methylase (Dam). **b** | In mammalian cells, the degradation of the mismatch-containing leading strand (green) might begin at the 3' terminus of the primer strand. Once the mismatch is removed, the polymerase resynthesizes the degraded region. Mismatch repair (MMR) in the lagging strand might remove an entire Okazaki fragment, with degradation commencing at either end. Extension of the fragment closest to the replication fork would replace the degraded one. Removal of the RNA termini of the Okazaki fragments, followed by ligation, would give rise to a continuous, error-free, lagging strand. **c** | Substrates used in the *in vitro* MMR assays<sup>14,15</sup>. These circular heteroduplexes contain a single-strand break that is either 5' or 3' from a mismatch, which lies within a recognition sequence of a restriction enzyme (RE), and therefore makes the molecule refractory to cleavage by this enzyme. Mismatch-provoked degradation of the discontinuous strand, followed by repair synthesis, restores the RE-cleavage site. Adapted from reference #117.

Likewise, four MutL homologues are known in human cells (hMLH1, hMLH3, hPMS1, and hPMS2). Both types of homologues participate in the MMR in the form of heterodimers<sup>118</sup>. The different complexes and their known functions are described in Table 1.

A particularly interesting characteristic of hMutL and hMutS complexes is that hMLH1 and hMSH2 are stable by themselves, whereas hPMS1, hPMS2, and hMSH6 need the presence of the corresponding interacting partner to be stable (in absence of hMLH1: hPMS1, hPMS2; and in the absence of hMSH2: hMSH6, degrade). hMutL $\alpha$ , formed by hMLH1 and hPMS2, has the most important role in MMR (reviewed in<sup>121</sup>) and has been the most studied heterodimer. The role of hMutL $\gamma$  in MMR has also recently been investigated<sup>122-124</sup>.

As mentioned above, an important criterion that the MMR system has to satisfy is to direct the repair machinery to the mismatch-carrying newly synthesized strand. Interestingly, and different than in *E.coli* where MutH provides strand specificity by recognizing hemi-methylated GATC sequences, no MutH functional homologue has been found in other organisms. This fact may imply that the processing of mismatches that occur during replication could be triggered by strand breaks such as

the 5' or 3' termini of Okazaki fragments in the lagging strand, or the 3' terminus of the leading strand (Figure 16B).

The statement that something similar happens with mismatches arising during recombination, where the repair could be directed to the invading strand by its 3' terminus (Figure 16C) is supported by *in vivo*<sup>125, 126</sup> and *in vitro*<sup>120</sup> experimental work with MthH deficient *E.coli* and by human *in vitro* MMR assays<sup>127-129</sup>.

Based on the biochemical knowledge acquired so far, three different mammalian MMR models have been proposed: i) the molecular-switch model<sup>130</sup>, favors the stochastic bidirectional diffusion of multiple MutSα and MutLα sliding clamps from the mismatch. The repair process would start when a strand break tagged with other MMR features is encountered by clamps, ii) the active-translocation model<sup>131, 132</sup>, which hypothesizes that MutSα, probably with MutLα, after being released from the mismatch, translocates, in a controlled ATP hydrolysis-dependent manner, along the DNA, iii) the DNA bending/verification model, claims that MSH proteins remain in the proximity of the mismatch and, rather than protein movement along the DNA, is communication between the mismatch and the strand discrimination signal which involves DNA bending, although experimental evidences showed no satisfactory conclusions about that model<sup>133, 134</sup>. Since the first two models appear to be the most reliable ones, and because they only differ in the way MutSα is translated from the mismatch, they have been represented as one in Figure 17 (see Figure 17 legend for details).

### 3.2.3.2. MMR defects and cancer

There are two different classes of mutations derived from the inactivation of the MMR system and the consequent decrease in the repair rates of the total number of errors after DNA replication: simple nucleotide misincorporation, and strand misalignments.

Nucleotide misincorporations take place when DNA polymerase incorporates an erroneous base creating a mismatch (for example, incorporation of thymine opposite to guanine giving as a result a G/T mismatch) which escapes 3'-5' exonuclease proofreading activity. When the MMR system is not mutated, it recognizes the mismatch and repairs it. In cells with a deficient MMR system, the mismatch is not recognized resulting in a G:C to T:A transversion mutation incorporated in half of the progeny DNA.

Strand misalignments are due to slippage of the DNA polymerase complex during replication. This phenomenon is predominantly frequent in microsatellite sequences (i.e., short repetitive sequences) and generates "insertion/deletion" loops which are recognized and repaired by MMR. If not repaired, such misalignments lead to frameshift mutations. Based on experimental work with MMR-deficient cells, the most recurrent mutation is the loss of one unit in mononucleotide and dinucleotide repeats. Such an event is known as microsatellite instability (MSI)<sup>135, 136</sup>, and represents a hallmark of MMR-deficient tumors.

To give uniformity to MSI analysis, a panel of five microsatellite markers, two mononucleotide repeats (BAT25 and BAT26) and three dinucleotide repeats (D2S123, D5S346, and D17S250), known as Bethesda markers, are most commonly used<sup>137</sup>. According to these markers, the degree of microsatellite instability of a tumor can be high (MSI-H), when two or more markers show instability, or low (MSI-L), when microsatellite is detected in fewer markers. Cells carrying defects in MMR genes have increased the risk of malignant transformation.

Several anticarcinogenic functions of MMR genes are compromised in MMR-deficient cells: First, decreased genome stability, manifested as MSI all over the genome<sup>138, 139</sup>. Second, loss of heterology-dependent suppression of recombination, a fact that implies gene conversion and exposure of tumor suppressor genes to loss heterozygosity<sup>140</sup>, or chromosomal translocations<sup>141</sup>. Third, increased mutation rates in critical "target genes" (i.e., those with short microsatellite sequences in their coding sequences) involved in growth suppression<sup>142</sup>, apoptosis<sup>143</sup>, signal transduction<sup>144, 145</sup>, etc., resulting in growth advantage for the cells. MMR defects have been related to both hereditary and sporadic colon cancers (discussed in 3.2.4. and 3.2.5.), as well as to sporadic cancers in other organs called "sporadic tumors of the HNPCC spectrum" and "sporadic tumors not belonging to the HNPCC spectrum", respectively<sup>146</sup>.

### 3.2.4. Hereditary Syndromes

The familial form of colorectal cancer has become a major public health problem due to its relatively high frequency among western population. From the total number of CRC cases, ~80% are sporadic (see 3.2.5.), and ~20% are familial or inherited forms<sup>147</sup>.

Among the familial cases, i) 10-15% are probably caused by gene mutations and polymorphisms of low penetrance, of which the I1307K polymorphism in the APC gene is the best

example, ii) ~1% are tumors with chromosomal instability (CIN), with a tendency to appear on the left side colon, showing aneuploid DNA, carrying characteristic mutations (in *APC*, *KRAS*, and *p53*), and behaving aggressively, being familial adenomatous poliposis (FAP) the most common example, and iii) between 5% and 8% are tumors classified as HNPCC based on the Amsterdam and Bethesda criteria, (Figure 18).

Figure 18. The molecular mechanisms of sporadic and hereditary colorectal carcinogenesis.

Among the HNPCCs, accounting for 3-5% of total CRC, there are cases with germline mutations in one allele of a MMR gene (predominantly in *hMLH1* and *hMSH2*, but also in *hMSH6*, and *hPMS2* genes). These cancers show MSI, arise predominantly on the right side colon, with diploid DNA, harboring characteristic mutations (in *TGFBR2*, and *BAX*), and behaving less aggressively. The remaining HNPCC and HNPCC-like cases are still molecularly unexplained. Several important studies have contributed to the increase in our knowledge about these hereditary syndromes and many reviews have put together what is known thus far<sup>44, 71, 102, 121, 137, 146-161</sup>.

Below, FAP will be briefly described and HNPCC will be more extensively discussed.

In **FAP** patients, numerous (hundreds, even thousands) adenomas arise, mainly in the epithelium of the colon, at an early age. If not removed, the initial benign lesions undergo malignant degeneration by the age of 40 to 50 years in most of the patients (~100%).

FAP is due to germline mutations in the *APC* gene. Although the polyps are inherently benign, the first step of the two-hit hypothesis<sup>162</sup> has already taken place: the inherited *APC* mutation. Often, the remaining wild type (wt) allele is mutated or deleted, accelerating the generation of polyps. Further mutations (e.g. in *KRAS* or *p53*) to *APC*-mutated cells are much more likely to lead to cancer than they would in non-mutated epithelial cells.

When FAP results from mutations in the *APC* gene, it is inherited in an autosomal dominant (AD) pattern, which means one copy of the altered gene is sufficient to cause the disorder. In most cases, an affected person has one parent with the condition.

## HNPCC

Hereditary non-polyposis colorectal cancer syndrome, formerly known as Lynch syndrome, is the most common form of inherited predisposition to colon cancer.

It is characterized by the development of colorectal cancers but also by the apparition of endometrium cancer, and, less frequently, stomach, small intestine, urinary tract (kidney, renal pelvis, and ureter), ovary, and brain cancers<sup>147</sup>.

Table 2. **Amsterdam I and Amsterdam II Criteria.** Adapted from reference #144.

### Amsterdam I criteria

At least three relatives must have histologically verified colorectal cancer:  
 One must be a first-degree relative of the other two.  
 At least two successive generations must be affected.  
 At least one of the relatives with colorectal cancer must have received the diagnosis before the age of 50 years.  
 Familial adenomatous polyposis must have been excluded.

### Amsterdam II criteria

At least three relatives must have a cancer associated with hereditary non-polyposis colorectal cancer (colorectal, endometrial, stomach, ovary, ureter or renal-pelvis, brain, small-bowel, hepatobiliary tract, or skin [sebaceous tumors]):  
 One must be a first-degree relative of the other two.  
 At least two successive generations must be affected.  
 At least one of the relatives with cancer associated with hereditary non-polyposis colorectal cancer should have received the diagnosis before the age of 50 years.  
 Familial adenomatous polyposis should have been excluded in any relative with colorectal cancer.  
 Tumors should be verified whenever possible.

The early age of onset (between the age of 40 and 50) and the high penetrance (~80%), due to an autosomal dominant transmission trait, are the clinical hallmarks of this syndrome. Based on that, Amsterdam criteria I<sup>160</sup> and II<sup>161</sup> (Table 2), and Bethesda guidelines<sup>163, 164</sup> (Table 3) are the international diagnostic criteria for HNPCC. The Bethesda guidelines are more sensitive but less specific than the Amsterdam criteria in identifying HNPCC families with pathogenic mutations<sup>165, 166</sup>.

Another characteristic of HNPCC cases is acceleration in the carcinogenic process. In the general population, the adenoma/carcinoma transition takes 8 to 10 years, whereas an adenoma may emerge as a carcinoma in only 2 to 3 years in the HNPCC subjects<sup>151, 167</sup>.

Table 3. **Classical and revised Bethesda criteria.** Adapted from reference #156.

### Classical Bethesda criteria

1. Individuals with two HNPCC-related cancers, including synchronous and metachronous colorectal cancers or associated extra-colonic cancers (endometrial, ovarian, gastric, hepatobiliary, small bowel cancer or transitional cell carcinoma of the renal pelvis or ureter).
2. Individuals with colorectal cancer and a first degree relative with colorectal cancer and/or HNPCC-related extra-colonic cancer and/or colorectal adenoma; one of the cancers diagnosed at age <45 years, and the adenoma diagnosed at age <40 years.
3. Individuals with colorectal cancer or endometrial cancer diagnosed at age <45 years.
4. Individuals with right-sided colorectal cancer with an undifferentiated pattern on histopathology diagnosed at age <45 years.
5. Individuals with signet-ring-cell-type colorectal cancer diagnosed at age <45 years.
6. Individuals with adenomas diagnosed at age <45 years.

### Revised Bethesda criteria

1. Colorectal cancer diagnosed in a patient <50 years of age.
2. Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors<sup>a</sup>, regardless of age.
3. Colorectal cancer with MSI-H histology diagnosed in a patient <60 years of age.
4. Individual with colorectal cancer and one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers diagnosed under age of <50 years.
5. Individual with colorectal cancer and two or more first-degree or second-degree relatives with HNPCC-related tumors, regardless of age

<sup>a</sup>HNPCC-related tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter, renal pelvis, biliary tract, and brain tumors, sebaceous gland adenomas and keratoacanthomas in Muir-Torre syndrome and carcinoma of the small bowel

As mentioned before, a substantial portion of the HNPCC cases carry a germline mutation in one allele of a MMR gene (*hMLH1*, *hMSH2*, *hMSH6*, or *hPMS2* genes) whereas the molecular mechanism responsible for the remaining HNPCC and HNPCC-like cancers is still unknown. I will focus my attention on the first group.

Such mutations are detected in ~80% of HNPCC families<sup>168-170</sup>, primarily affecting *hMLH1* (~50%), *hMSH2* (~40%), and *hMSH6* (~10%), and less frequently *hPMS2*<sup>171</sup> and *hMLH3*<sup>172</sup> (Table 4).

**Table 4. Genes associated with HNPCC predisposition by virtue of heritable mutations found in those genes. Adapted from reference #143.**

Gene	Phenotypic Features Associated With Germline Mutations
MLH1	Mostly typical HNPCC. ~30% of mutations are of the missense type whose phenotypic manifestations may vary.
MSH2	Mostly typical HNPCC. Extracolonic cancers may be more common than in MLH1 mutation carriers. A major gene underlying Muir-Torre syndrome.
MSH6	Typical or atypical HNPCC. Often characterized by late onset, frequent occurrence of endometrial cancer, distal location of colorectal cancers, and low degree of MSI in tumors.
PMS2	Typical or atypical HNPCC. The penetrance of mutations may vary. A major gene underlying Turcot's syndrome.
MLH3	Mostly atypical HNPCC. May be characterized by distal location of colorectal cancers and variable degree of MSI in tumors.
EXO1	Mostly atypical HNPCC. May be associated with MSI in tumors.

Abbreviations: HNPCC, hereditary nonpolyposis colon cancer; MSI, microsatellite instability.

These mutations, called “first hit”, are not enough to cause MSI, but a “second hit”, or somatic mutation, which inactivates the wt allele of the gene, turns on the mutator phenotype (the mutator phenotype is a hypothesis that postulates that the mutation rate in the early stages of tumor development must be significantly greater than that of normal somatic cells) and the subsequent MSI. If the mutation is located in an intergenic region of the gene it may have no biological relevance, but if it is sited in a coding region causing a frameshift mutation, biological consequences emerge.

Inactivation of genes involved in signal transduction (*TGFR2*)<sup>142</sup>, and apoptosis (*BAX*)<sup>143</sup> by deletions in poly(A) repeats of their codon regions, favors cell transformation rather than cell death, therefore cancer progression. Other genes have been reported to be altered in lower frequency (*IGFR2*)<sup>173</sup>, *TCF4*<sup>174</sup>, *AXIN2*<sup>145</sup>, *GARE*<sup>175</sup>, and *B2M*<sup>176</sup>.

Although these lesions have aggressive histological characteristics (such as poor cell differentiation), their prognosis is quite favorable due to lower rates of metastatic potential<sup>146, 177, 178</sup>. This fact could be explained by i) the high number of cytotoxic T-lymphocytes present in these tumors, which, activated by the mutated peptides of the cancer cell surface, trigger tumor cell apoptosis, and ii) a lower MMR-deficient cell viability due to spontaneous mutagenesis, although the molecular mechanisms of this event are still unclear.

The evolution of the two inherited CRC syndromes discussed above, shows interesting variations. In FAP, thousands of benign tumors form after *APC* mutation. Each of them slowly progresses to malignancy, requiring the sequential accumulation of mutations in *KRAS* and *p53*, etc. Among so many adenomas, some of them will progress to cancer. When not treated, the median age of cancer diagnosis is 42 (the same as in HNPCC), 25 earlier than the median age of sporadic colorectal cancer patients.

**Figure 19. Comparison of the Development of Cancer in FAP and HNPCC Patients** FAP results from an increased rate of tumor initiation due to abrogation of the gatekeeper function of APC. In contrast, the mismatch repair defect in HNPCC results in an enhanced rate of mutation that greatly accelerates tumor progression but results in near normal rates of tumor initiation. That the rate of tumor initiation is nearly normal in HNPCC patients is indicated by the fact that such patients do not have a greatly increased incidence of adenomas, in striking contrast to FAP patients (Lynch et al., 1996). But FAP and HNPCC patients both develop colorectal cancers at a median age of 42 years, suggesting that tumor progression is as rate-limiting for cancer formation as is tumor initiation. Adapted from reference #44.

In HNPCC, adenomas form at approximately the same rate as in the general population. Nevertheless, the adenomatous cells with the MMR defect gain mutations at a rate two of three orders of magnitude higher than in normal cells. The accumulation of mutations in tumor suppressors and oncogenes leads to a rapid progression to cancer. Therefore, FAP can be considered as a disease of tumor initiation and HNPCC one of tumor progression (Figure 19).

### 3.2.5. Sporadic CRC

Around 10% of all sporadic colorectal cancers show MSI. Differently from HNPCC tumors, in which MMR genes are mainly inactivated by mutations, MSI in sporadic CRC is nearly totally due to epigenetic inactivation of *hMLH1* expression by promoter hypermethylation<sup>179</sup>.

Experimental work with cell lines showed that the hypermethylation affects, and thus inactivates, both alleles at the same time<sup>180</sup>. The fact that this phenomenon is already present in non-neoplastic colorectal mucosa and colorectal adenomas, suggests that it is an early event in the process of cancer growth<sup>179, 181, 182</sup>.

As mentioned before, CRC can be defined as MSI-H (high degree of MSI), MSI-L (low degree of MSI), and MSS (microsatellite-stable tumors). The group of MSI-H colorectal cancers include tumors that; i) arise predominantly on the proximal colon, ii) have diploid DNA content, iii) are poorly differentiated, and iv) have better survival<sup>183-186</sup>. The clinicopathological characteristics do not seem to be able to distinguish MSI-L from MSS tumors<sup>187-189</sup>, but there is not an agreement about whether MSI-L tumors should be considered separate from MSS tumors or not.

On the other hand, it has been shown that methylation inactivates other genes besides *hMLH1*.

Hence, tumors in sites other than the colon can appear through different tumorigenic pathways. Despite this fact, the histology and biology of such tumors are very similar, thus, they are identified as “sporadic tumors of the HNPCC spectrum” (Table 5).

Table 5. Involment of the MMR genes in sporadic tumors of the HNPCC spectrum. Adapted from reference #143.

A considerable portion (2% to 50%<sup>137, 146, 178</sup>) of other sporadic cancers (breast, prostate, lung, bladder, and others), known as “sporadic tumors not belonging to the HNPCC spectrum”, also carry MMR defects (Table 6). Among these tumors, and different from HNPCC and sporadic tumors of the HNPCC spectrum, MMR defects do not seem to start the malignant process because they arise in late stages of tumorigenesis. Nevertheless, MSI status can still be used as a genetic prognostic marker in these cancers to choose the optimal therapeutic strategies for each case.

However, around 90% of the sporadic colorectal cancers do not carry MSI. The sequential model for CRC genesis<sup>71</sup> (Figure 20) claims that mutations in the APC gene, and less frequently in the beta-catenin-encoding gene and AXIN2, are required for tumor initiation. Subsequent progression towards malignancy is accompanied by other mutational alterations, affecting oncogenes (KRAS), tumor suppressor genes (p53), and other unknown genes, as well as epigenetic events<sup>190</sup>.

**Figure 20. Genetic model of colorectal carcinogenesis**  
Mutations in APC, β-catenin or axin genes are required for tumour initiation. Subsequent progression towards malignancy is accompanied by genomic instability and sequential mutations in K-ras, Smad4, p53 genes, as well as in other unknown genes. Adapted from reference #24.

Tumor progression is driven by the selection of specific genetic (and epigenetic) alterations that accumulate in strict order. In fact, whereas mutation events are random, the order in which they accumulate is non-random, supporting robustly the theory that only certain mutations confer selective advantage to a tumor to progress depending on its stage.

Adenomas are the precancerous lesions from which the malignant tumors arise. The malignant potential of an adenoma depends on its size, histologic type, and degree of atypia. Adenomatous polyps larger than 1 cm, with a large villous histologic component or with severe dysplasia have an increased frequency of malignant change. Only around 10-15% of these polyps progress to cancer and such progression generally takes around ten years. In MMR-deficient HNPCC patients, this progression period is reduced to approximately two years. Colorectal polyps are usually asymptomatic, frequently found during screening for colorectal cancer, and removed via colonoscopy. This procedure is adequate for most adenomas, including those with severe grade of dysplasia. The polyps which during exploration are found to be malignant may require surgical resection to ensure the complete elimination of cancer cells.

Colon cancer staging is an estimate of the condition of a particular cancer for diagnostic and research purposes. The systems for staging colorectal cancers largely depend on the extent of local

invasion, the degree of lymph node involvement, and whether there is distant metastasis. The most common currently used system for staging is the TNM system (Figure 21A). Since the number of combinations of categories is high, combinations are grouped to stages for better analysis (Figure 21B and C).

The aims for adopting a global standard staging system are to i) aid medical staff in staging the tumor and thus helping to plan the treatment, ii) give an indication of prognosis, iii) assist in the evaluation of the results of treatment, and iv) enable facilities around the world to collect information more productively.

Figure 21. **Colorectal cancer staging system.** (A) The different categories of the TNM staging system, (B) Stages of the TNM system (based on grouped combinations of categories), (C) Graphic representation of different tumor staging through cancer progression.

## 4. RESULTS (summary of the publications)

**“Transcriptome profile of human colorectal adenomas”** [Jacob Sabates-Bellver\\*](#), Laurens G. van der Flier\*, Mariagrazia de Palo, Elisa Cattaneo, Caroline Maake, Hubert Rehrauer, Endre Laczko, Michal A. Kurowski, Janusz M. Bujnicki, Mirco Menigatti, Judith Luz, Teresa V. Ranalli, Alfredo Pastorelli, Roberto Faggiani, Marcello Anti, Josef Jiricny, Hans Clevers and Giancarlo Marra. *In press, Molecular Cancer Research*. \*These authors contribute equally to this work (**Appendix I**).

The objectives of this study were to characterize the global gene expression changes occurring during the transition from the normal to the adenomatous epithelium in the colon and to identify novel biomarkers of these tumors.

Using a standardized microarray platform covering the entire human genome, we analyzed the transcriptional features of 32 prospectively collected colorectal adenomas, each with matched samples of normal mucosa.

We first showed that the expression profiles of the adenomas could be easily distinguished from that of the normal mucosal samples by using different unsupervised analyses.

Gene Ontology analysis revealed that the biological processes more frequently represented by genes found up-regulated in adenomas were *mitosis*, cell division, DNA replication and spindle organization, whereas *host immune defense*, inorganic anion transport, organ development and inflammatory response were the most over-represented processes by genes found down-regulated in this lesions.

Since the Wnt signalling pathway is the physiological regulator of epithelial homeostasis, we performed a gene expression analysis of all the genes presently considered involved in this pathway. We found out that almost half of them (45%) showed statistically significant expression changes in adenomas, whereas 34% remained unchanged and 21% were expressed neither in the normal colorectal mucosa nor in the adenomas.

Using Canonical Correspondence Analysis (a supervised variant of the Correspondence Analysis), we correlated the gene expression profiles with the clinico-pathological characteristics of the adenomas. This analysis revealed that the expression profile of adenomas with a diameter >20 millimetres could be easily distinguished from that of smaller adenomas. This observation is relevant because the dimension of the adenomas is considered an prognostic factor. We are in the process of identifying the gene expression changes that are more relevant to the growth of adenomas.

We then focused on *KIAA1199*, a gene encoding a protein with an unknown function. This gene was over-expressed ~55 and ~39 fold in adenomas and carcinomas, respectively. We showed that *KIAA1199* expression level significantly correlate with that of many well known Wnt target genes. Furthermore, its expression was down-regulated after induction of dominant negative TCF4, beta-catenin siRNA, or N-terminal deleted TCF4 mutant, all of them inhibitors of the Wnt-pathway, suggesting its Wnt target status. These evidences confirmed the results obtained in our previous work (“The intestinal Wnt/TCF signature”, Appendix II).

By *in situ* hybridization and immunohistochemistry we showed that KIAA1199 mRNA and protein were predominantly expressed in the proliferating compartment of normal intestinal crypts, with much higher expression levels in dysplastic and neoplastic glands. This expression pattern is reminiscent of that of many Wnt target genes. KIAA1199 was expressed in the cytoplasm, particularly in the luminal side of the dysplastic cell multilayer.

Based on our data, we concluded that KIAA1199 is a novel biomarker of colorectal neoplasia and displays potential as an interventional target.

**“The intestinal Wnt/TCF signature”** Laurens G. Van der Flier\*, Jacob Sabates-Bellver\*, Irma Oving, Andrea Haegebarth, Mariagrazia de Palo, Marcello Anti, Mareille E. van Gijn, Saskia Suijkerbuijk, Marc Van de Wetering, Giancarlo Marra and Hans Clevers. *Gastroenterology* 2007; **132**:628-32.

\*These authors contribute equally to this work (**Appendix II**).

The goal of this publication was to describe a core target gene program, the Wnt/TCF signature gene set, responsible for the transformation of human intestinal epithelial cells.

Comparing the transcriptome of two colorectal cancer cell lines (stably transfected with dominant negative TCF4 or TCF1 to block the Wnt signalling pathway) with that of colorectal adenomas, adenocarcinomas and normal mucosa (where the Wnt signalling pathway is abnormally activated), we found out new target genes of this pathway.

We identified new putative Wnt target genes related to the different stages of carcinogenesis; adenomas, adenocarcinomas, and both tumor conditions (51, 36 and 121 genes, respectively).

By *in situ* hybridization on *Apc<sup>min</sup>* mice (these mice carry a mutant *Apc* allele, developing multiple adenomas, primarily in the small intestine), and based on the staining patterns observed in the crypts, the putative Wnt target genes could be grouped in three different categories. Genes in the first category were expressed in the proliferative compartment of the crypts. Approximately half of the genes displayed a gradient of decreasing signal along the base of the villus. For the remaining genes in this category, mRNA expression was restricted to the proliferative compartment of the crypt proper with a steep gradient towards the crypt-villus junction. The second category comprised Paneth cell maturation markers. In the third category we found genes whose staining pattern is limited to 1-5 crypt cells near the crypt bottom, where the crypt stem cells have been mapped previously.

Basically, the Wnt/TCF signature gene set defines the core program activated by TCF4 in intestinal epithelial cells. The individual genes within the signature represent promising targets for therapy of colorectal cancer, since their expression is consistently activated as the direct result of oncogenic Wnt pathway mutations, while many target genes will be causally involved in the transformed behavior of the neoplastic cells.

**“Defective DNA Mismatch Repair Determines a Characteristic Transcriptional Profile in Proximal Colon Cancers”** Massimiliano di Pietro\*, [Jacob Sabates Bellver\\*](#), Mirco Menigatti, Fridolin Bannwart, Annelies Schnider, Anna Russell, Kaspar Truninger, Josef Jiricny and Giancarlo Marra. *Gastroenterology* 2005; 129:1047-1059. \*These authors contribute equally to this work (**Appendix III**).

The aim of this study was to characterize the transcriptional profile of mismatch repair deficient (MMR-) colon carcinomas, which represent a sub-group of colon cancers with peculiar molecular, pathologic and clinical features (microsatellite instability, conspicuous lymphocytic infiltration, preferential localization in the proximal colon, and better prognosis).

In an unsupervised analysis of microarray data, we showed that MMR status (MMR- or MMR+) was the most important variable which allowed an almost perfect clustering separation of the proximal colon cancers included in our series. We identified a *MMR-status signature* of 100 genes, whose gene expression changes perfectly segregated the MMR+ cancers from the MMR- deficient ones and that most likely explain the clinico-pathological differences between these two kinds of colon cancers.

We also identified gene expression alterations, relative to expression in normal colon mucosa, specific to mismatch repair deficient (MMR-) or mismatch repair proficient (MMR+) colon cancers. We named this group of 39 genes the *MMR-related tumorigenesis signature*.

In order to isolate the changes more likely localized in the epithelial-cell component of the colon cancers (avoiding a possible dilution effect due to presence of stroma) we compared the gene expression profiles of the cancers with those of the colon cancer epithelial cell lines. Genes with similar expression changes (MMR+ > MMR- or MMR- > MMR+) in the cancer samples and the colon cancer cell lines presumably reflect an epithelial-cell specific alteration. We designated this group of 54 genes as the *MMR-related epithelial-cell signature*.

Since genetic alterations caused by MMR deficiency itself (e.g., microsatellite instability within the coding or regulatory regions of genes expressed by cancerous epithelial cells) might lead to some of the transcriptional differences seen between MMR- and MMR+ cells, we analyzed the frequency of microsatellites in the cDNAs of the genes contained in the MMR-related epithelial-cell signature by comparing them to 100 control genes. We found out that microsatellites consisting of  $\geq 8$  repeat units in the coding region and/or in the 5'UTR and /or  $\geq 12$  repeat units in the 3'UTR were significantly more common and longer in the *MMR-related epithelial-signature* genes than those observed in control genes. We suspected that MSI in these microsatellites might affect the stability of the transcripts. We confirmed microsatellite instability in repeats of the 3'UTR of three genes found differently expressed in MMR- cancers: *NUTF2*, *HNRPL* and *CTNNB1*.

Due to the conspicuous lymphocytic infiltration characteristic of MMR- cancers, we focused on genes involved in the immune response against tumor cells. By using real-time RT-PCR, we confirmed the high mRNA levels of *4-1BBL* (*TNSFS9*), a gene that plays a crucial role in the anti-tumor response, in MMR- cancers. Furthermore, the high expression of this gene was associated with a high expression of the corresponding protein in MMR-deficient colon cancer cell lines studied by flow cytometry. We proposed 4-1BBL as a biomarker of MMR-deficient colon cancers and suggest its

potential as a target for therapeutic drugs development supported by the fact that it is not expressed in the cells of the colon normal mucosa.

Finally, we compared the transcriptome of colon cancers (independently of their MMR status) with that of the colon normal mucosa to find out genes important for colon carcinogenesis in general. We find 182 genes with significantly different expression levels between normal mucosa and colon cancers with a fold change  $\geq 4$ . The involvement of many of these genes in colon carcinogenesis has been reported in previous studies, but a number of gene expression changes are novel findings.

It is worth mentioning that microarray data were obtained using the HG-U95v2 arrays from Affymetrix, which contain approximately 12000 probes. However, we have recently hybridized the same RNA samples with Affymetrix HG-U133plus2.0 arrays, which contain oligonucleotides representing the entire human genome. These new results will give us a much wider perspective on the gene expression changes in colon cancer (these data will be the subject of a different study).

**“The transcriptome of ileal and colonic normal mucosa”** Jacob Sabates-Bellver, Tobias Gonzenbach, Endre Laczko, Hubert Rehrauer, Caroline Maake, Fridolin Bannwart, Annelies Schnider, Josef Jiricny and Giancarlo Marra. Manuscript in preparation (**Appendix IV**).

The aim of this study was to obtain a comprehensive comparative transcriptional analysis of human colon and ileum normal mucosa tissues to find out genes and pathways responsible for the different incidence of adenocarcinomas (in colon is much higher than in ileum) in these two GI tracts considered so far rather similar in morphology and cellular organization.

Twelve paired colonic and ileal normal mucosa samples from 12 patients were used for microarray data analysis. Different unsupervised analyses of the transcriptional levels of the expressed genes effectively segregate the two groups.

We performed Gene Ontology analysis with the list of genes whose expression in the two parts of the GI tract differed significantly. We found that the genes more expressed in colon were primarily implicated in the positive regulation of cell motility and cell migration while those more expressed in ileum were principally associated to different aspects of metabolism, protein kinase C activation and regulation of apoptosis, among others.

Because several signalling pathways maintain the cellular homeostasis in the GI epithelium, we looked for changes in the expression levels of genes involved in these pathways, as well as of numerous transcription regulators.

The Wnt signalling pathway is the physiological regulator of epithelial homeostasis and has been described that the transformation process to adenoma, and lately to carcinoma, begins in the epithelial crypts as a result from qualitative, quantitative and spatial subversion of this pathway. For this reason, we also searched for differently expressed genes involved in this pathway.

Given that cell renewal rates in ileum and colon are very high and that apoptosis plays a key role in this process, we focused our attention on the apoptosis-related genes, particularly in the

expression levels of *CIDEB* and *CIDEC*, two members of the cell death-inducing DFFA-like effectors family. We have found a significant over-expression of these two genes in ileum compared with colon normal mucosa. Interestingly, *CIDEB* and *CIDEC* mRNA expression levels were further down-regulated in adenomas and adenocarcinomas of the colon. We are currently analyzing their expression at the protein level.

These preliminary results suggest that *CIDEB* and *CIDEC* may play an important role in colorectal tumorigenesis prevention.

**“Expression of the MutL Homologue hMLH3 in Human Cells and its Role in DNA Mismatch Repair”** Elda Cannavo, Giancarlo Marra, [Jacob Sabates-Bellver](#), Mirco Menigatti, Steven M. Lipkin, Franziska Fisher, Petr Cejka and Josef Jiricny. *Cancer Res* 2005; 65 (23): 10759-66 (**Appendix V**).

In this paper, we showed the participation of *hMLH3* in MMR *in vitro* and its partial redundancy with *hPMS2*, which would be an explanation for the low penetrance of *hPMS2* mutations in hereditary nonpolyposis colon cancer families (HNPCC families).

A polyclonal antibody against the COOH terminus of *hMLH3*, which contains the *hMLH1*-interacting domain, was raised to avoid the inconvenient caused by the fact that the commercially available *hMLH3* antibodies could detect the recombinant protein on WB but failed to detect the endogenous protein in all the human cell lines used in this study.

After having established that the level of *hMLH3* in human cells is not dependent on *hMLH1* and that correlates with *hMLH3* mRNA, we wondered whether the fluctuation of *hMLH3* expression in the tested cell lines could be linked to the well known gene silencing process by cytosine methylation. The CpG island present in the promoter was found to be methylated giving the mechanism to explain, although this is not the only one, the lack of expression of *hMLH3*.

Given that *hMLH3*, *hPMS2* and *hPMS1* interact with the same region of *hMLH1*, the correlation between the relative abundance of the three different heterodimers and the phenotype of the human cells was assessed. We showed that *hMLH3* is less abundant than *hPMS1* and *hPMS2*.

We also showed how, differently from *hPMS2* and *hPMS1*, the presence of *hMLH1* is not required for the stabilization of *hMLH3* in human cells, although it is necessary in baculovirus-infected Sf9 cells.

Finally, we speculated that physiologic levels of *hMutLy* might not be sufficient to mediate mismatch correction *in vivo* although in our *in vitro* MMR assays, the factor could participate in the correction of base-base mispairs and one-nucleotide insertion/deletion loops.

My direct contribution to this article was concentrated at the RNA level of *hMLH3* in cell lines, producing the microarray data. We could show a correlation between the RNA and the protein levels of *hMLH3* in the different cells used in this study.

## 5. Conclusions and perspectives

This section is divided in four different parts, each of them related to one of the projects of my thesis (see results and appendixes).

### Transcriptome profile of human colorectal adenomas

Our data represents the first comprehensive transcriptomic analysis of these precancerous lesions, and provide evidences of the existence of a broad-scale transcriptome remodeling during adenoma formation.

Expression data subjected to four different unsupervised analyses - Hierarchical clustering, Principal component analysis, Correlation analysis, and Correspondence analysis- effectively segregated the normal tissues from the adenomas.

Furthermore, the expression profile of adenomas measuring > 20 mm was easily distinguished from those of smaller (= 20 or < 20 mm) adenomas. As expected, larger diameters were correlated with high-degree dysplasia.

We have focused on a series of changes we consider crucial in adenomatous transformation in particular those involved in i) regulation of transcription, ii) cell proliferation, cell differentiation and apoptosis, iii) cell adhesion, and iv) the Wnt signaling pathway.

We have identified *KIAA1199* as a novel target of the Wnt signaling pathway based on several evidences: i) its protein expression at the bottom of the intestinal crypts where the proliferative compartment is placed, ii) its up-regulation in adenomas and carcinomas compared to normal mucosa, and iii) its down-regulation after blocking the beta-catenin/TCF transcription complex in CRC cell lines. Due to the over-expression in colon tumors and to its membrane's surface localization, we also proposed *KIAA1199* as a new molecular biomarker of colorectal tumors with capabilities of being a potential interventional target.

Because the function of *KIAA1199* is still unknown, our next objectives are to find out i) the regulation mechanisms of its expression, ii) the morphological and molecular changes triggered by its up- or down-regulation in cell lines, iii) the phenotype of *KIAA1199* knock-out animal models, iv) whether its up-regulation is specifically linked to colorectal tumors or common to other cancerous lesions.

We will also analyze transcriptional changes between colorectal adenomas and carcinomas in order to track expression changes along the entire transformation process from normal mucosa to invasive cancer.

### The intestinal Wnt signaling pathway

To identify new Wnt target genes is a subject of great interest to better understand cancer progression. On this regard, we have performed a combined transcriptomic analysis using colorectal cancer cell lines, normal mucosa, adenoma, and carcinoma colon samples, to identify new targets of this pathway. With this approach (see Appendix II), we have found putative Wnt target genes related

to the different progression stages of the carcinogenic process. We classified these genes, based on their expression localization, in three different groups: i) genes expressed in the proliferative compartment of the crypts. Approximately half of the genes displayed a gradient of decreasing signal along the base of the villus. For the remaining genes in this group, mRNA expression was restricted to the proliferative compartment of the crypt proper with a steep gradient towards the crypt-villus junction, ii) Paneth cells maturation markers, and iii) putative stem cells markers, i.e., genes whose staining pattern was limited to 1-5 crypt cells near the crypt bottom.

At this point, as we did for *KIAA1199*, these putative Wnt target genes should be individually validated with other techniques (such as Northern blotting, *in situ* hybridization, reporter gene experiments, ChIP on chip, immunohistochemistry, etc) to prove that their expression is certainly regulated by this pathway.

### Transcriptional profile of mismatch repair deficient colon cancer

In order to find out molecular alterations related to the MMR status, we conducted a gene expression profile analysis by comparing the transcriptome of MMR-deficient with that of the MMR-proficient tumors and cell lines.

We identified a *MMR-status signature* of 100 genes, whose gene expression changes perfectly segregated the group of MMR+ cancers from that of MMR- deficient.

Gene expression alterations specific to mismatch repair deficient (MMR-) or mismatch repair proficient (MMR+) colon cancers, relative to expression in normal colon mucosa, were also identified and named as *MMR-related tumorigenesis signature*.

A *MMR-related epithelial-cell signature* containing epithelial-cell specific alterations was as well identified.

Our data showed several changes that might explain the better prognosis associated with MMR-deficient colon cancers. Compared with MMR-proficient cancers, MMR-deficient tumors presented reduced transcript levels of several genes with functions that presumably favor tumor progression and increased expression of factors believed to inhibit tumor growth, progression, and/or invasiveness.

Among the genes found to be more expressed in MMR-deficient tumors, we identified *4-1BBL* (*TNSFS9*), a key player in the anti-tumoral response mechanism, as a biomarker of this type of cancers. Given that *4-1BBL* is not expressed in the colon normal mucosa, its over-expression in MMR-deficient lesions could be exploited for a novel therapeutic approach in this subgroup of colon cancers.

We suspected that some of the expression changes might conceivably reflect transcriptional effects of MSI within the coding or regulatory regions of genes expressed by cancerous epithelial cells, and we confirmed such hypothesis by the finding of a higher frequency of microsatellites in the complementary DNAs of the MMR-related epithelial cell signature genes compared with that of randomly selected expressed.

The microarray platform we used screened only ~10000 genes. We have recently repeated the analysis using an array that covers the entire human genome. These new data confirmed our previous results and brought to light other significant gene expression changes. We are currently

analyzing the list of genes obtained to select interesting candidates for further investigation. We are also planning to combine these data with the information obtained from a brand new type of array, called Exon Array, which reveals alternative splicing of the genes.

### **The transcriptome of ileal and colonic normal mucosa**

Although morphology and cellular organization in different tracts of the lower GI tract are considered quite similar, physiology and cancer incidence are strikingly different. Thus, we performed a transcriptome analysis in ileum and colon normal mucosa tissues in order to identify gene expression patterns that might offer new work hypotheses to achieve a better molecular understanding of these differences.

Amongst the genes significantly changed between the two groups, we focused on those involved in transcription regulation, cell proliferation/differentiation, Wnt signaling pathway, and apoptosis.

In the apoptosis-related list of genes, we found the cell death-inducing DFFA-like effectors *CIDEB* and *CIDEC* markedly more expressed in ileum than in colon. In addition, these two genes were further down-regulated in adenomas and adenocarcinomas of the colon. We are currently checking whether the *CIDEB* and *CIDEC* proteins are also differentially expressed in the two epithelia and how their expression is distributed along the crypt-villous axis. Based on these experiments, we will evaluate the feasibility of a new project aiming to verify whether the modulation of *CIDEB* and *CIDEC* expression in mouse ileum and colon might modify the incidence of adenocacinoma in these two tissues.

The analysis of genes involved in signaling pathways controlling the cellular homeostasis in the intestinal mucosa, such as Notch, TGF-beta, BMP, Hedgehog, or RAS/RAF, is also in progress.

**Keywords:** colorectal adenomas; transcriptome; Wnt signaling; KIAA1199.

**Abstract**

**Background:** Colorectal cancers are believed to arise predominantly from adenomas. Although these precancerous lesions have been subjected to extensive clinical, pathological, and molecular analyses, little is currently known about the global gene expression changes accompanying their formation.

**Results:** To characterize the molecular processes underlying the transformation of normal colonic epithelium, we compared the transcriptomes of 32 prospectively collected adenomas with those of normal mucosa from the same individuals. Important differences emerged not only between the expression profiles of normal and adenomatous tissues, but also between those of small and large adenomas. A key feature of the transformation process was the remodeling of the Wnt pathway reflected in patent over- and underexpression of 78 known components of this signaling cascade. The expression of 19 Wnt targets was closely correlated with clear upregulation of *KIAA1199*, whose function is currently unknown. In normal mucosa, *KIAA1199* expression was confined to cells in the lower portion of intestinal crypts, where Wnt signaling is physiologically active, but it was markedly increased in all adenomas, where it was expressed in most of the epithelial cells, and in colon cancer cell lines, it was markedly reduced by inactivation of the  $\beta$ -catenin/TCF(s) transcription complex, the pivotal mediator of Wnt signaling.

**Conclusions:** Our transcriptomic profiles of normal colonic mucosa and colorectal adenomas shed new light on the early stages of colorectal tumorigenesis and

identified *KIAA1199* as a novel target of the Wnt signaling pathway and a prominent early marker of colorectal adenomatous transformation.

## Background

In developed countries, sporadic adenomatous colorectal polyps are found in roughly one third of asymptomatic adults below the age of 50 who undergo colonoscopy. Depending on their characteristics (multiplicity, size, histological features, degree of dysplasia), these lesions can be associated with a substantial risk of recurrence (up to 60% at three years) and the development of advanced neoplastic disease [1]<sup>(and additional references herein)</sup>. It has been estimated that 15% of all adenomas measuring 1 cm or more will progress to carcinomas within 10 years of their detection [2].

Although adenomatous polyps are not the only precancerous lesions in the colorectum, they are the most common, and they are the precursors of most of the cancers in this organ. In these neoplasms, the transformation process begins in the epithelial crypts and seems to result from qualitative, quantitative, and spatial subversion of the Wnt-signaling pathway, the physiological regulator of epithelial homeostasis [3-5]. This adenoma-carcinoma pathway of tumorigenesis is characterized by mutations involving various components of this pathway (e.g., *APC*, whose germline mutations are responsible for familial adenomatous polyposis, a cancer-predisposition syndrome that accounts for ~0.5% of colorectal cancers [6]; *CTNNB1*, which encodes a subunit of the cadherin protein complex known as  $\beta$ -catenin; and *Axin*, the gene encoding a multidomain scaffold protein that is essential for  $\beta$ -catenin degradation). The result of these mutations is an accumulation of  $\beta$ -catenin, first in the cytoplasm and then in the nucleus, where it associates with DNA-

binding proteins of the T-cell factor (TCF)/lymphoid-enhancer factor (LEF1) family, transforming them from transcriptional repressors into transcriptional activators that affect the expression of numerous genes involved in epithelial homeostasis.

Although the key role played by adenomatous polyps in colorectal tumorigenesis is widely acknowledged, the gene expression changes that trigger or accompany their development have never been comprehensively studied. We therefore conducted a transcriptomic analysis of prospectively collected colorectal adenomas, using a standardized oligonucleotide microarray covering the entire human genome. This study not only provided new information that is fundamental for future molecular characterization of these precancerous lesions, it also allowed us to identify a novel biomarker of colorectal tumorigenesis.

## **Results**

The focus of our study was the adenoma-adenocarcinoma pathway of colorectal carcinogenesis, which is closely linked to deregulation of the Wnt signaling pathway. To gain insight into the early steps of this process, we confined our investigation exclusively to sporadic (i.e., non-familial), pedunculated colorectal adenomas (type *0-1p* of the Paris classification [7]). Nonpolypoid and sessile polypoid lesions were not included because in some cases their transformation is believed to proceed along non-adenomatous pathways [8]. Details on our case selection criteria are provided in Materials and Methods.

Thirty-two pedunculated adenomatous polyps, each with matched samples of normal mucosa, were prospectively collected from 28 patients (**Table 1**). The total number of synchronous and previously excised adenomas was < 3 in 18/28 patients and 3-15 in the remaining ten. In this latter subgroup, the absence of *APC*- or *MYH*-associated multiple adenomatosis had been confirmed by genetic testing. Histological analysis of one polyp (case NM) revealed superficial infiltration of the submucosa, but this case was not excluded since the region sampled for microarray analysis was clearly adenomatous. (As noted below, this finding was consistent with the results of hierarchical cluster analysis shown in Additional data file 1.)

Analysis of microarray data for the 32 adenoma/normal mucosa tissue pairs revealed that 31,033 of the probes were expressed in one or both of the tissue groups. The normal tissues were effectively segregated from the adenomas in four unsupervised analyses of the expression levels of these genes [hierarchical clustering, principal component analysis (PCA), correlation analysis and correspondence analysis (CA); see Materials and Methods for details] (**Figure 1**). In a separate analysis, these two tissue groups were also unequivocally distinguished from a previously described set of 25 colon cancers [9], which we reanalyzed for this study with the same microarray used to characterize the adenomas and normal mucosa (**Additional data file 1**).

Almost half of the expressed probes (15,059 / 31,033) displayed significant expression changes in adenomas. This finding was not unexpected since the two tissue types are characterized by dramatic histological differences. Some of the

observed changes undoubtedly reflect the different proportions of epithelial and stromal cells in the two tissues rather than real transcriptional changes in the neoplastic epithelium. However, we devised a sampling procedure (see Materials and Methods for details) that allowed us to obtain samples containing a high percentage of epithelial-cell RNA of high quality and in amounts large enough to require only a single round of amplification. As a result, we did not need to resort to microdissection, which in our experience considerably reduces the quality of the extracted RNA. The complete microarray data sets are available (one of the public repositories). Our analysis focused almost exclusively on expression differences that were  $\geq 2$ -fold since less marked changes were more likely to be non-relevant to the pathogenesis of adenomas.

Probes with fold changes  $\geq 2$  (1190 probes upregulated and 2469 downregulated in adenomas) were subjected to gene ontology analysis to identify the biological processes involved in the transition of normal mucosa to adenoma. The most significant results of this analysis are listed in **Additional data file 2**. The processes that were most markedly over-represented among genes that were upregulated in adenomas included *mitosis*, *DNA replication* and *spindle organization*. Downregulated genes were predominantly involved in *host immune defense*, *inorganic anion transport*, *organ development*, and *inflammatory response*, even though a small group of genes involved in the latter process were upregulated in adenomas (**Additional data file 3**).

We then analyzed the transcript levels of 319 genes believed to be components of the complex Wnt signaling pathway (**Additional data file 4**). Sixty-six of these genes (21%) were not expressed in either the normal or adenomatous tissue, and 34% were expressed similarly in both tissue groups. The remaining 144 genes - almost half (45%) of those linked to the Wnt pathway - displayed significantly altered expression in adenomas, and 78 / 144 displayed fold changes of  $\geq 2$ .

A supervised extension of CA [10], canonical correspondence analysis (CCA), was then used to identify possible correlations between gene expression patterns and clinical or pathological variables. Four of the variables considered (*adenoma diameter*, *colon segment of origin*, *degree of dysplasia*, and *adenoma recurrence* - see Table 1) were clearly associated with distinct clusters of expression profiles (**Figure 2, panel A**). The profile of adenomas measuring  $> 20$  mm could be easily distinguished from those of smaller ( $= 20$  or  $< 20$  mm) adenomas (**Figure 2B**). It is interesting to note that *adenoma diameter* was closely correlated with (i.e., its vector in panel A is almost parallel to) CCA axis 1, which represents the most important proportion of the total variance. Larger diameters were correlated with high-degree dysplasia, as would be expected.

The CCA plot of the 11,709 modeled probes (loading plot, not shown) suggested that the distinction between the three size groups of adenomas is due to a complex network of relatively small changes in the expression of numerous genes (as opposed to marked changes involving a limited number of genes). Nevertheless, to maximize the use of the extensive data sets, we selected the 500 probes with the

highest loading scores along the CCA axis 1 and isolated a set of genes whose expression changes displayed significant positive or negative correlation with adenoma size (**Additional data file 5**). Although their association with adenomas must be validated in a larger series, these are the expression changes most likely to play causal roles in the progression of these tumors.

It should be mentioned that normal mucosa from the sigmoid colon had an expression profile that differed significantly from that of tissues from other colon segments (**Figure 2A**). This finding will be explored in a future study conducted on a large series of normal mucosa samples from different colorectal segments.

The transcriptional profile of the 32 adenomas was thoroughly analyzed to identify genes likely to be involved in the development and evolution of these lesions. One of the first features that attracted our attention was the marked upregulation of *KIAA1199*, a gene encoding a protein with unknown function. Its overexpression was striking in all 57 colorectal tumors we examined (average increases of 54.8-fold in adenomas and 38.8-fold in carcinomas [9], compared with normal mucosa). These findings were fully confirmed by real-time RT-PCR analysis of RNA extracted from samples used for the microarray study and from additional samples collected after the present study was completed (**Additional data file 6**).

In light of these findings, it was natural to wonder whether *KIAA1199* might be a novel positively regulated target of Wnt signaling, which is characteristically deregulated in colorectal tumors. Previous microarray studies indicated that genes co-regulated at the transcriptional level under different conditions tend to be involved

in the same processes and pathways, and the analysis of transcriptional co-expression has been used to predict the function of novel genes [11-13]. Therefore, we conducted a search for known Wnt targets (listed in **Additional data file 7**) among the genes whose expression patterns in all the tissue samples significantly correlated with those of *KIAA1199*. (The procedure used in this analysis is summarized in Materials and Methods and **Additional data file 8**.) Forty-nine percent of the known Wnt targets that were overexpressed in our adenoma samples had expression patterns that were positively correlated with that of *KIAA1199* (**Figure 3, panels A and B**), as opposed to only 7.9% of the overexpressed genes that are not considered Wnt targets ( $p < 0.0001$ ).

Evidence of the potential involvement of *KIAA1199* in the Wnt signaling pathway had also emerged from another study by our group (Van der Flier et al., *Gastroenterology*, in press). A combined analysis of microarray data of tissues and cell lines placed *KIAA1199* at the top of a list of genes (Supplementary Table 1 of Van der Flier et al.) that were upregulated in colorectal adenomas and downregulated in colon cancer cell lines that had undergone stable transfection with doxycycline-inducible forms of dominant negative TCF(s) (dnTCF1 or dnTCF4) to suppress Wnt signaling [14, 15]. In the present study, *KIAA1199* was also found to be markedly downregulated in LS174T colon cancer cells in which Wnt signaling had been blocked by the induction of  $\beta$ -catenin siRNA or N-terminal deleted TCF4 [15, 16]. The dramatic decrease in *KIAA1199* mRNA levels associated with this inhibition of the Wnt pathway was confirmed by Northern blotting (**Figure 3C**).

In general, Wnt target genes are expressed predominantly in the proliferating compartment of normal intestinal crypts (lower portion), and their expression is appreciably increased in adenomatous glands [15]. Our analysis of human tissues with preserved architecture indicated that these are also attributes of *KIAA1199*. In *in situ* hybridization studies, *KIAA1199* mRNA was detectable only in the lower portion of normal colonic epithelial crypts (**Figure 4A and B**), and its expression levels were much higher in dysplastic glands (**Figure 4C**). These patterns were confirmed at the protein level by immunohistochemistry performed with an antibody raised in our laboratory (**Figure 4D-K**). This analysis also revealed that the *KIAA1199* is a cytoplasmic protein whose expression is most intense near the cell membrane, particularly on the luminal side of the dysplastic cell multilayer (**Figure 4F-K**).

## Discussion

Adenomatous colorectal polyps are one of the most common human tumors and the most frequent precancerous lesions in the colorectum, but their transcriptome has been only partially analyzed, and the data are generally based on a limited number of cases [17-19]. We attempted to fill this gap by performing a comprehensive whole-genome microarray analysis of a large, highly homogenous set of adenomas that was collected prospectively.

A comparison of the transcriptomes of adenomatous polyps and segment-matched samples of normal colorectal mucosa revealed evidence of broad-scale

remodeling. As a starting point for future verification studies, we have drawn up a list of 478 genes that were significantly up- (n=153) or downregulated (n=325) in the adenomatous tissues (fold changes of 4 or more) (**Additional data file 9**). Space constraints preclude more than a cursory examination of this list, but we have highlighted in **Table 2** certain aspects that we feel are particularly interesting in terms of their relevance to the process of adenoma formation. For instance, transcription regulation appears to be extensively modified. Twenty-nine molecules involved in this process were expressed in adenomas at levels > 4 higher or lower than those observed in the normal mucosa, but there were also a number of smaller changes in this category (**Additional data file 10**) that might also have dramatic effects on gene expression. Several other alterations are noteworthy in terms of their potential impact on cell proliferation, differentiation, apoptosis, and cell adhesion: 1) Upregulation of four members of the REG (*Regenerating*) family of genes [20, 21], which would lead to increased tissue-mitogen expression; 2) Upregulation of *LCN2* [22] and downregulation of *ZFHX1B/SIP-1* [23] in the absence of significant changes in the expression of the epithelial cadherin *CDH1* (E-cadherin), which would prevent or delay the epithelial-mesenchymal transition. (Changes were also noted in the expression of other cell-adhesion genes of the cadherin and claudin families, including the striking overexpression of the placental cadherin gene *CDH3*, which is associated with early events in the transformation process [24, 25]); 3) Downregulation of *ZFHX1B/SIP-1* and *Max dimerization protein 1* (*MXD1/MAD1*) (decreased only 3.3 fold and therefore not listed in Table 2) [26, 27] and

overexpression of the *RTEL1* helicase, which should facilitate telomere elongation [28]; 4) Alterations that would diminish apoptosis, e.g., overexpression of the decoy receptor for Fas ligand, *TNFRSF6B*, which is reportedly co-regulated with *RTEL1* on chromosome 20q13.3 [29-31]; decreased expression of the netrin-1 receptor, *UNC5C* [32]; and expression changes involving three Fas apoptosis inhibitory molecules (*FAIM*), including *FAIM1*, which was increased 2.3-fold and is thus not listed in Table 2; 5) Marked downregulation of several genes that would result in reduced tumor-suppression activity, e.g., those encoding the anti-angiogenic factor ANGPTL1 [33], the cyclin-dependent kinase inhibitor CDKN2B/p15, and the prostaglandin catabolism enzyme HPGD [34]. It is also important to recall the size-related differences noted in the adenoma gene expression profiles (Figure 2 and Additional data file 5). When validated in a larger series of tumors, these differences should provide important clues to the molecular basis of the well known link between the dimensions and malignant potential of colorectal adenomas [1].

Our study also furnishes a complete picture of expression changes involving gene components of the Wnt pathway across the transition from normal to adenomatous epithelium (Additional data file 4), as well as evidence for the existence of a novel Wnt target: *KIAA1199*. This gene, which encodes a protein of unknown function, was strikingly overexpressed in all the adenomas included in this study and in 25 adenocarcinomas of the colon described in a previous report [9]. Even more intriguingly, its expression was significantly correlated with that of several genes that are well established targets of Wnt signaling. Our hypothesis that *KIAA1199* is

upregulated by the TCF(s)/ $\beta$ -catenin transcription complex was considerably strengthened by the marked decreases in *KIAA1199* expression observed in cultured colorectal cancer cells when the Wnt pathway was inhibited by overexpression of dominant negative TCF4 proteins or by  $\beta$ -catenin knock-down. It is not yet clear whether this is a direct effect, but this possibility is supported by the results of a recent genome-wide TCF4 ChIP-on-chip analysis, which indicates that the *KIAA1199* locus is surrounded by four TCF4-bound regions (Hatzis, van der Flier and Clevers, unpublished).

Other features of *KIAA1199* expression are also compatible with its putative role as a Wnt target gene. *KIAA1199* mRNA and protein are both confined to the proliferative compartment of normal intestinal crypts, where Wnt signaling is normally active, and they are highly overexpressed in colorectal adenomas and carcinomas, where this pathway is almost always aberrantly activated.

In normal and tumor tissues, *KIAA1199* is expressed in the cytoplasm of epithelial cells. In glands with low-degree dysplasia, higher concentrations are observed in the mucin vacuoles of goblet cells, but cytoplasmic expression of the protein in tumor cells remains elevated even after goblet-cell differentiation has been lost (Figure 4). These features, together with *KIAA1199*'s localization in the luminal portion of the cytoplasm, are suggestive of a secreted and/or membrane protein. This conclusion is consistent with our *in silico* analysis of *KIAA1199* (see **Additional data files 11 and 12**), which strongly predicts the presence of a signal peptide at its N-terminal end. In addition, the central region of *KIAA1199* contains a TMEM2-

homology domain, which is present in a number of eukaryotic proteins, including TMEM2, polyductin (PKHD1), and fibrocystin L (PKHD1L1) (**Figure 5**), all large receptor proteins characterized by an N-terminal signal peptide or a single trans-membrane helix and a short cytoplasmic tail [35].

A study based on yeast two-hybrid screens suggested that KIAA1199 may interact with plexin A2 (KIAA0463) [36]. The trans-membrane plexins interact with trans-membrane semaphorins on nearby cells, providing “stop” and “go” signals that are crucial for cell motility and invasive growth [37, 38]. KIAA1199/plexin A2 interaction could thus play important roles in colorectal tumorigenesis, not only in the invasive stages, but also earlier during the formation of abnormal glands in benign adenomas.

A recent report linked high levels of *KIAA1199* mRNA with cell mortality in human fibroblasts and in a renal-cell carcinoma cell line [39]. In that study, however, there was no significant increase in *KIAA1199* expression during replicative aging of mortal cells, and this finding contrasts with the documented behavior of other genes involved in cell aging [40]. Furthermore, the authors reported wide variation in *KIAA1199* mRNA expression in breast cancer cell lines, and this finding raises the possibility that expression of this gene *in vivo* and in cell lines may differ.

## **Conclusions**

We believe that our microarray data will serve as a springboard and reference point for other studies on the molecular basis of colorectal transformation

along the adenoma-carcinoma pathway (and subsequently for the study of alternative pathways as well). Some of the transcriptional changes reported in this study might one day be used as molecular indices of the susceptibility of adenomas to malignant transformation, information that would be helpful in planning appropriate follow-up of the lesions. As for KIAA1199, its invariably high expression in the colorectal tumors we studied raises interesting possibilities for the development of a new molecular biomarker for the diagnosis of these neoplasms. For example, since KIAA1199 expression in the normal mucosa is limited to cells in the lower portion of the crypts, which are not yet programmed to be shed into the intestinal lumen, the presence of KIAA1199 peptides in fecal water might prove to be a specific marker of adenomatous lesions. In addition, although due consideration must be given to its probable physiological role(s) in intestinal crypts and possibly in a number of other human tissues [39, 41, 42]), KIAA1199 may be a potential target of antibody-based therapies.

## **Materials and Methods**

### *Tumor samples*

Pedunculated colorectal polyps and normal mucosa were obtained during colonoscopies carried out in the Gastroenterology Unit of the Belcolle City Hospital in Viterbo, Italy. The tissues were collected prospectively with informed patient consent and the approval of the local Human Research Ethics Committee. Patients with documented familial polyposis, with > 15 adenomatous polyps (total: synchronous +

previously excised) [6], or currently treated with non-steroidal anti-inflammatory drugs (including aspirin) were excluded from the study.

For each polyp, three biopsies of normal mucosa were collected from the same colon segment ( $\geq 2$  cm from the site of the polyp). Immediately after removal, a small sample of epithelial tissue (5-15 mg) was cut from the tip of each polyp, leaving the underlying *muscularis mucosae* intact. We excluded polyps  $< 1$  cm to ensure that the sampling procedure would not interfere with the histologic diagnosis. All polyp samples were collected by a single operator (MdP) using the same procedure to minimize artifacts due to sampling differences. The approach used allowed us to obtain specimens with a high percentage of epithelial cells without resorting to microdissection, which can diminish the quantity and quality of the extracted RNA.

The polyp sample and the three normal mucosal biopsies were immersed in *RNAlater* (Ambion, Huntington, UK) for subsequent microarray analysis, and the remainder of the polyp was submitted for pathological analysis. The cut surface at the tip was labeled with India ink so that the sampled area could be easily identified during routine histologic examination. The tissue was then fixed in buffered formalin and embedded in paraffin. DNA extracted from sections of this specimen was also used to rule out microsatellite instability (reflecting defective DNA mismatch repair) at the *BAT26* locus, as previously described [43]. All of the polyps included in the study met the following criteria: type *0-1p* [7]; maximum diameter: 1-4 cm; absence

of surface ulceration; histological diagnosis of adenoma; absence of microsatellite instability at *BAT26*.

In some analyses, we also included transcriptomic data from a previously described set of 25 colon cancers (mismatch repair-proficient and -deficient) [9], which we re-analyzed for this study with the same microarray used to characterize the adenomas and normal mucosa.

*Microarray analysis, real-time RT-PCR, and Northern blotting*

Total RNA was extracted (RNeasy Mini kit, Qiagen) from homogenized tissue samples (5- to 15-mg), and its integrity was verified by capillary gel electrophoresis (Bio Analyzer, Agilent Technologies). Complementary RNA (15 µg / sample), synthesized and labeled as previously described [9, 44], was hybridized with the Affymetrix U133 Plus 2.0 array (High Wycombe, UK), which contains *in situ* synthesized oligonucleotides representing the entire human genome (54,675 probes).

Raw gene-expression data generated by GCOS software (Affymetrix) were imported into the GeneSpring software program (Agilent) and normalized per chip (i.e., to the median of all values on a given array) and per gene (i.e., to the median expression level of the given gene across all samples). Analysis was performed using the log expression values with GeneSpring's cross-gene error model turned on. Probes were excluded from analysis unless they were listed as "present or marginal calls" and/or had expression values  $\geq 100$  in 50% or more ( $\geq 16 / 32$ ) of the samples in at least one of the tissue groups (adenomas, normal mucosa).

Expression data were subjected to four different unsupervised analyses: 1) Hierarchical clustering using the Pearson correlation coefficient as a similarity measure and the average linkage algorithm for branch merging; 2) Principal component analysis (PCA), which reduces the dimensionality (number of variables) of a data set while retaining most of its variance [9]; 3) Correlation analysis, which involved computation of Pearson correlation coefficients for all possible sample pairs and visualization of correlation values as tile plots; 4) Correspondence analysis (CA), another dimension-reducing method [45], that was used to identify samples associated with particular gene expression levels. In typical CA, a matrix of  $n$  gene-expression levels from  $p$  samples is treated as a two-way contingency table (genes by samples or vice versa) with  $n$  and  $p$  specifications for the "factors" gene and sample, respectively. Each intensity value thus reflects the abundance of a given transcript in a given sample. Like PCA, CA identifies independent "factorial components" that account for variance within a multidimensional gene data set, but in this case the components are identified and ranked according to the correlation between gene and sample scores. A supervised or constrained extension of CA [10], canonical correspondence analysis (CCA), was then used to identify possible correlations between gene expression patterns and clinical or pathological variables. CA and CCA, as well as the corresponding plots, were computed using R software and the *ade4* and *made4* packages furnished by Bioconductor (<http://www.bioconductor.org>.)

The Mann-Whitney test was used to select genes differentially expressed in normal mucosa and adenomas; Benjamini-Hochberg multiple testing correction was applied with a false-discovery rate of 0.01. The genes in this set that were differentially expressed with fold differences of  $\geq 2.0$  were then analyzed with ErmineJ software [46] to identify any biological processes from the Gene Ontology database [47] that were over-represented.

Pearson correlation was used to identify correlation between *KIAA1199* expression and the expression of other genes in the entire set of tissue samples. Fisher's exact test was used to identify possible over-representation of known Wnt targets among genes whose expression was closely correlated with that of *KIAA1199* (correlation values  $\geq 0.8$ ).

RT-PCR and Northern blotting were performed as previously described [44, 48] to verify the expression level of *KIAA1199* in tissue samples and in LS174T colon cancer cells in which inducible inhibition of the Wnt pathway had been achieved with previously described methods [14-16].

#### *In situ hybridization*

Digoxigenin-labeled *KIAA1199* antisense riboprobes were synthesized from a PCR product amplified from human colon cDNA with *KIAA1199*-specific primers (sense: 5'cacatcggggaggagataga3'; antisense, containing a T7 RNA polymerase-binding site: 5'taatcagactcactatagggttcagacttgaca3'). This product was transcribed *in vitro* using the DIG RNA labeling kit and T7 RNA polymerase (Roche Diagnostics, Rotkreuz, Switzerland). *In-situ* hybridizations were performed on paraffin-embedded

sections of human colon fixed with 4% buffered formalin as described elsewhere [49].

#### *Immunohistochemistry*

Our *in silico* analysis of KIAA1199 (see Additional data file 11) indicated that residues 202-217 (IHSDRFDTYRSKKESE) form a loop between a conserved  $\beta$ -strand and the following helix of the N-terminal GG domain. This charged, surface-exposed peptide was used to raise a rabbit polyclonal antibody, which was purified by affinity chromatography on Thiopropyl Sepharose 6B (Amersham, Piscataway, NJ) derivatized with the antigenic peptide. A 1:1000 dilution of this antibody was used, as previously described [43], to evaluate KIAA1199 expression in formalin-fixed, paraffin-embedded sections of adenoma and normal mucosal tissues.

#### **Author contributions**

J.S-B. performed microarray analyses, antibody production, and other experiments as part of his PhD thesis; L.G. VdF. performed studies with cell lines and Northern blotting; M.dP. performed tissue sampling in adenomas and collected clinical data as part of her internship in Gastroenterology; E.C. performed extraction of nucleic acids and immunohistochemistry; C.M. performed in situ hybridizations; H.R performed image and data analysis and most of the statistical analyses; E.L. performed

correspondence and canonical correspondence analyses; M.A.K. and J.M.B performed *in silico* analysis of the KIAA1199 protein; M.M. and J.J. extracted nuclei acids, performed microsatellite analysis, and contributed to real-time RT-PCR experiments; T.V.R and V.G. independently analyzed and histologically classified tumor samples; A.P. and R.F. performed endoscopies with polypectomy and patient follow-up; M.A. enrolled patients, directed the clinical part of the study, and served as supervising mentor for M.dP.; J.J. and H.C. conceived and designed important experiments during the study and contributed to the writing of the manuscript; G.M. conceived the project, prepared the manuscript, and served as supervising mentor for J. S-B. during his PhD. Funding for this project came from the Zurich Cancer League and the Swiss National Science Foundation.

### **Acknowledgments:**

We are grateful to the patients who participated in this study; to R. Haider, E. Pani, T. Lehmann, A. Patrignani, and U. Wagner for technical assistance; to A. Mueller, E. Veljkovic, and F. Bannwart for critical reading of the manuscript; and to M. Kent for editorial assistance. This study was supported by the Zurich Cancer League and the Swiss National Science Foundation.

## Figure Legends

### **Figure 1: Unsupervised analyses of microarray data**

**(A) Hierarchical clustering analysis:** The 64 tissue samples represented on the x-axis include 32 normal mucosal samples (green branches) and 32 adenomas (red branches). Each probe plotted on the y-axis is color-coded to indicate the gene's level of expression relative to its median expression level across the entire tissue-sample set (blue: low; red: high). In the adenoma dendrogram, branches representing individual samples and small groups merge at higher levels than those of the normal-mucosa dendrogram, reflecting lower-level correlation, i.e., higher variability among the adenoma specimens. **(B) Principal component analysis (PCA).** Profile plot of the normalized first principal component (PCA-1) across the 64 specimens (green dots: normal mucosa; red dots: adenomas). The two tissue groups differ significantly in terms of PCA-1 ( $p < 0.0001$ ), which accounted for 26% of the total variance. Note the higher variability of the PCA-1 values in the adenoma group (higher fluctuation). **(C) Correlation analysis.** Tile-plot visualization of the pairwise correlations of the samples. Correlation values are indicated on the gray-scale column (white > black: high > low). High correlation is observed among the samples

within each group (upper right quadrant: adenomas; lower left quadrant: normal mucosa) although the adenomas displayed somewhat greater diversity (i.e., on the whole, the gray tones in the upper right quadrant are darker than those in the lower left quadrant). Normal and adenoma samples are poorly correlated (upper left and lower right quadrants). However, samples from the same patient generally showed higher correlation than that observed between normal and adenoma samples from different patients (bright pixels on the secondary diagonals in the upper left and lower right quadrants). This finding probably reflects the strong influence of several factors, including the individual genetic background and life-style, and the fact that the normal and adenomatous tissues from a given patient were from the same colon segment. **(D)** *Correspondence analysis (CA)* of mRNA log(intensity) values of expressed genes from 27 of the 32 tissue pairs (normal mucosa: green dots, adenoma: red dots). The other five pairs were excluded from this analysis because one of the two samples behaved as an outlier. Limiting our analysis to the more homogeneous pairs facilitated the comparison of the gene expression profiles for the two tissue groups and allowed more reliable identification of clinical/pathological variables associated with profile scatter (see Figure 2). The areas delimited by the ellipses represent 95% of the estimated bi-normal distribution of the sample scores on the first and second CA axes. The map of the sample scores on the first two axes shows that CA efficiently discriminates between normal and adenoma samples. Higher variability is evident in the adenoma group, where the samples are more widely dispersed.

**Figure 2: Clinical/pathological variables that correlate with distinct gene expression profiles.** The panels summarize the most important results of the canonical correspondence analysis (CCA) of mRNA intensity log-ratio values (adenoma : normal) of expressed genes. For clarity, CCA axis 1 has been drawn vertically in both panels. A: Correlation between specific clinical/pathological variables (*adenoma diameter, colon segment of origin, degree of dysplasia, adenoma recurrence*) and clusters of differential gene expression profiles (coded as log-ratio profiles), like those shown in panel B. Each vector represents a specific value for a given variable (e.g., *adenoma diameter*: > 20 mm, *dysplasia*: high-degree, etc.) and points toward the center of the profile cluster correlated with the clinical/pathological characteristic it represents. If the centers for each specific value are separated, the corresponding vectors point in distinct directions; otherwise, they are directed toward the same point. In the former case, the represented variable can be assumed to be significantly correlated with the profiles; in the latter case, there is no correlation. The length of the vector reflects the strength of the correlation: those approaching the circumference of the correlation circle, which represents a correlation value of 1, indicate stronger correlation than shorter vectors (correlation closer to 0). (Abbreviations: d, diameter; Hd, high-degree dysplasia; Ld, low-degree dysplasia; A, ascending colon ; T, transverse colon; D, descending colon; S, sigmoid colon; R, rectum; Rec, recurrent adenomas; no Rec, no recurrent adenomas). Unlabeled vectors are related to variables that were not clearly associated with any distinct

cluster of expression profiles. Larger adenomas were predictably associated with high-degree dysplasia. In contrast, their association with non-recurrence was unexpected and probably due to the fact that patients who had already undergone endoscopic polypectomy (i.e., those with recurrence) presented relatively recent-onset (consequently, smaller) polyps at the study colonoscopy. **B.** CCA score plot with samples grouped by *adenoma diameter*. Each of the three size-related groups is delimited by an ellipse with the center labeled. The ellipse representing the adenomas measuring > 20 mm in diameter shows very little overlap with those of the other two groups (adenomas with diameters of 20 mm and those with diameters < 20 mm).

**Figure 3: *KIAA1199* is a putative target of Wnt signaling.**

**(A)** Degree of correlation between the expression of *KIAA1199* mRNA and that of 19 known Wnt-signaling target genes identified with the procedure described in Methods, Results, and Additional data file 8. For each of the 20 genes, the graph shows the normalized intensity of expression level (plotted on the y-axis) in each of the 32 adenomas and corresponding samples of normal mucosa (x-axis). **(B)** Mean expression of each gene in normal mucosa (green dots) and adenomas (red dots). Bars: confidence interval. **(C)** Northern blot showing reduced *KIAA1199* expression in LS174T cells following doxycycline-mediated induction of  $\beta$ -catenin siRNA, dominant negative TCF4 (dnTCF4), or N-terminal-deleted TCF4 (N-TCF4). The ~ 8-Kb band corresponds to full-length *KIAA1199* mRNA. The lower band (~5 Kb) may

represent an alternative form of this mRNA. Dox: cell transfectants grown in the presence or absence of doxycycline; Tr1: a parental clone (i.e., cells expressing the repressor protein modified by doxycycline but not transfected with  $\beta$ -catenin siRNA, dnTCF4, or N-TCF4) used as a control of doxycycline exposure. As a loading control, the ethidium-bromide-stained agarose gel is shown in the lower panel.

**Figure 4: Expression of KIAA1199 mRNA and protein in normal intestinal mucosa and colorectal tumors.** *In situ* hybridization studies (panels A-C) localized KIAA1199 mRNA expression to the lower portion of normal epithelial crypts (**A, B**) and revealed that expression is markedly upregulated in colorectal tumors (**C**). Note the different levels of expression in tumor glands and normal crypts (\*). (**D**) KIAA1199 protein expression is also limited to the lower half of the normal colonic crypts, and a similar pattern is observed in the ileal mucosa (**E**), where the protein is expressed only in the crypts (not in the villi). In panels **F**) and **G**), adenomatous crypts with low-grade dysplasia present increased expression of KIAA1199, particularly in the cytoplasm facing the crypt lumen, and in and around the mucin vacuoles of goblet cells. (Note the striking difference with goblet cells of normal crypts in both panels.) The expression pattern changes dramatically during the transition from low-grade dysplasia with goblet-cell differentiation (**H**) to high-grade dysplasia in which this differentiation is no longer apparent (**I**, arrowheads: multilayer of unstained nuclei occupying more than the basal half of the dysplastic epithelium). In more advanced colon tumors (**J** and **K**), KIAA1199 overexpression is

maintained. Note that, in **J**) and **I**), the expression of KIAA1199 protein (like that of KIAA1199 mRNA – panel C) is highest in the luminal portion of the dysplastic glands. **L**) Normal mucosa, with the corresponding tumor in the inset. Negative control: KIAA1199 antibody pre-absorbed with the peptide used to immunize rabbits.

**Figure 5. Phylogenetic tree of the proteins containing the TMEM2-homology domain found in the central region of KIAA1199.**

The tree was generated with MEGA3 [50] from the multiple sequence alignment shown in Additional data file 12. It was calculated with the Minimum Evolution algorithm and the JTT matrix. Positions with gaps were removed for calculation of pairwise distances. Node robustness was assessed using the bootstrap method with 100 resamplings. (Bootstrap values are shown at the nodes.) Two branches emerged, one comprising KIAA1199 and TMEM2, and the other with polyductin, fibrocystin L, and a number of other THD-containing proteins found in the ciliate *Tetrahymena thermophila*, which were apparently generated in a series of *Tetrahymena*-specific gene duplications. The N-terminal repeats of polyductin and fibrocystin L clustered together, as did the C-terminal repeats, suggesting that the intragenic duplication of the TH domain in the ancestor of polyductin and fibrocystin L occurred before the divergence of chordates and echinoderms (more details in Additional data file 11).

**Table 1.** Characteristics of the 28 patients with adenomatous polyps included in the study

Patient	Age (y)	Sex	Colon Segment involved	Max. \* two adenomas from these patients were analyzed.

# LG and LS are brothers.

^ Low (L) vs. high-grade (H) dysplasia as defined by the World Health Organization Classification of Tumors of the Digestive System, Editorial and Consensus Conference in Lyon, France, November 6-9, 1999. International Agency for Research on Cancer (IARC); IARC Press, Lyon 2000.

§ Superficial submucosal invasion (T1). The tissue collected for microarray came from the adenomatous portion of the polyp.

¥ This number includes the adenoma(s) subjected to microarray analysis

‡ Total no. adenomas detected and excised during previous colonoscopies. (-): No previous colonoscopies

f These cases were considered as recurrent adenomas for the canonical correspondence analysis (CCA). In two of them (Ž), the index colonoscopy was performed in a different center about 10 years before the study colonoscopy.

~ Hyperplastic polyposis

M, male; F, female; A, ascending colon; T, transversum; D, descending colon; S, sigmoid colon; R, rectum; T, tubular; T-V, tubulo-villous.

**Table 2.** Genes most likely to be involved in the development and evolution of colorectal adenomas (a subset of genes listed in Additional data file 9) subdivided by Gene Ontology category.

Gene Symbol	Gene Name	Fold Differences *	
		▲	▼
<b>Regulation of Transcription</b>			
NLF1	nuclear localized factor 1	33.1	
FOXQ1	forkhead box Q1	24.4	
MSX2	msh homeobox homolog 2	22.2	
ASCL2	achaete-scute complex-like 2	17.3	
MSX1	msh homeobox homolog 1	8.5	
IRX3	iroquois homeobox protein 3	8.4	
GRHL3	grainyhead-like 3	7.9	
TRIM29	tripartite motif-containing 29	7.4	
ETV4	ets variant gene 4 (E1A enhancer binding protein, E1AF)	5.4	
ARNTL2	aryl hydrocarbon receptor nuclear translocator-like 2	5.3	
TEAD4	TEA domain family member 4	5.2	
SP5	Sp5 transcription factor	5.2

MUCDHL	mucin and cadherin-like		5.1
PCDH9	protocadherin 9		4.9
L1CAM	L1 cell adhesion molecule		4.2

\* Overexpressed (▲) or underexpressed (▼) in adenomas (vs. normal mucosa samples)

**Additional data files**

Additional data file 1 contains Supplementary Figure 1, which shows the unsupervised hierarchical clustering of the normal colonic mucosa, colorectal adenomas, and colorectal carcinomas. Additional data file 2 contains Supplementary Table 1 with the gene-ontology biological-process categories significantly over-represented in the set of genes differentially expressed in adenomas. Additional data file 3 contains Supplementary Figure 2 with tile plots showing the differential expression in adenomas (vs. normal mucosa) of genes involved in different biological processes. Additional data file 4 contains Supplementary Table 2 reporting the differential expression of known Wnt signaling genes in normal colorectal mucosa and colorectal adenomas. Additional data file 5 contains Supplementary Table 3, which reports a selection of genes whose expression displayed significant positive or negative correlation with adenoma size. Additional data file 6 contains Supplementary Figure 3 with data regarding the amplification of *KIAA1199* mRNA by real-time RT-PCR. Additional data file 7 contains Supplementary Table 4 with the list of known Wnt target genes. Additional data file 8 contains Supplementary Figure 4 showing the procedure used to analyze the degree of co-expression between *KIAA1199* and known Wnt target genes. Additional data file 9 contains Supplementary Table 5, which reports the list of genes with markedly altered expression in colorectal adenomas (fold differences of 4 or more compared with normal mucosa). Additional data file 10 contains Supplementary Table 6 reporting the transcript level in adenomas of genes classified as transcription regulators.

Additional data file 11 contains supplementary text presenting a detailed *in silico* analysis of the KIAA1199 protein. Additional data file 12 contains Supplementary Figure 5 showing the sequence alignment of the TH domain for the region 406-1087 of the human KIAA1199 protein.

Figure 4

Figure 5, Sabates-Bellver et al.

Figure 5

Supplementary Figure 1. Sabates-Bellver et al.

**Supplementary Figure 1.** Unsupervised hierarchical clustering of normal colonic mucosa (32 samples, green branches), colorectal adenomas (32 samples, red branches), and advanced colorectal carcinomas (25 samples, black branches) based on transcriptome analysis with Affymetrix U133 Plus 2.0 arrays. Data were analyzed as described in Methods. The 32,813 probes plotted on the y-axis (i.e., those expressed in at least one of the three tissue groups) are color-coded to indicate their expression levels relative to the median level for the gene across the entire sample set (blue: lower; red: higher). As expected, the tissue sample collected from patient NM's polyp (\*) clustered with the adenomas. This sample was clearly adenomatous although the polyp itself was classified as a T1 tumor (Table 1).

**Supplementary Table 1:** Biological-process categories most significantly over-represented in the set of genes differentially expressed in adenomas (vs. normal mucosa) with fold differences of 2.0 or more (ErmineJ's overrepresentation analysis)

<b>EFNA1</b>	ephrin-A1	2.3
<b>EFNA5</b>	ephrin-A5	1.7
<b>EGFR</b>	Epidermal growth factor receptor (v-erb-b oncogene homolog, avian)	2.0
<b>EMP1</b>	epithelial membrane protein 1	2.3
<b>ENPP2</b>	ectonucleotide pyrophosphatase/phosphodiesterase 2 (autotaxin)	2.0
<b>EPHA10</b>	EPH receptor A10	1.5
<b>EPHA3</b>	EPH receptor A3	9.5
<b>EPHA7</b>	EPH receptor A7	5.0

Supplementary Table 2 (page 3)

<i>EPHA8</i>	EPH receptor A8	1.3
<i>EPHB6</i>	EPH receptor B6	1.4
<i>FGF9</i>	fibroblast growth factor 9 (glia-activating factor)	3.8
<i>FN1</i>	fibronectin 1	4.1
<i>FOSL2</i>	FOS-like antigen 2	1.5
<i>FRZB</i>	frizzled-related protein ( <i>SFRP3</i> )	2.6
<i>FZD1</i>	frizzled homolog 1 (Drosophila)	2.0
<i>FZD4</i>	frizzled homolog 4 (Drosophila)	1.5
<i>FZD5</i>	frizzled homolog 5 (Drosophila)	2.5
<i>FZD8</i>	frizzled homolog 8 (Drosophila)	2.4
<i>GCG</i>	glucagon	68.5
<i>HDGFRP3</i>	Hepatoma-derived growth factor, related protein 3	1.7
<i>HHEX</i>	homeobox, hematopoietically expressed	2.2
<i>IGF1</i>	insulin-like growth factor 1 (somatomedin C)	4.0
<i>ISLR</i>	immunoglobulin superfamily containing leucine-rich repeat	2.4
<i>KLF5</i>	Kruppel-like factor 5 (intestinal)	1.5
<i>L1CAM</i>	L1 cell adhesion molecule	4.2
<i>LRRFIP2</i>	Leucine rich repeat (in FLII) interacting protein 2	2.6
<i>MAPK10</i>	mitogen-activated protein kinase 10	1.9
<i>MGC39518</i>	hypothetical protein MGC39518	1.9
<i>MITF</i>	microphthalmia-associated transcription factor	2.2
<i>NIN</i>	ninein (GSK3B interacting protein)	1.5
<i>NLK</i>	Nemo-like kinase	1.6
<i>POSTN</i>	periostin, osteoblast specific factor	3.8
<i>PPARD</i>	peroxisome proliferative activated receptor, delta	1.8
<i>PPP2CB</i>	protein phosphatase 2 (formerly 2A), catalytic subunit, beta isoform	1.3
<i>PRKCB1</i>	Protein kinase C, beta 1	4.1
<i>PRKCD</i>	protein kinase C, delta	1.8
<i>PRKCE</i>	Protein kinase C, epsilon	1.5
<i>PRKCH</i>	Protein kinase C, eta	1.7
<i>PRKCZ</i>	protein kinase C, zeta	1.2
<i>PTTG1IP</i>	pituitary tumor-transforming 1 interacting protein	1.6
<i>RET</i>	ret proto-oncogene	1.6
<i>RHOU</i>	ras homolog gene family, member U	2.2
<i>SFRP1</i>	secreted frizzled-related protein 1	7.6
<i>SFRP2</i>	secreted frizzled-related protein 2	3.9
<i>SLC9A3R1</i>	solute carrier family 9, member 3 regulator 1	2.7
<i>SMAD1</i>	SMAD, mothers against DPP homolog 1 (Drosophila)	1.7
<i>SMAD3</i>	SMAD, mothers against DPP homolog 3 (Drosophila)	1.5
<i>SMAD4</i>	SMAD, mothers against DPP homolog 4 (Drosophila)	1.5
<i>SNAI2</i>	snail homolog 2 (Drosophila)	3.8
<i>SNF1LK2</i>	SNF1-like kinase 2	1.6
<i>SOSTDC1</i>	sclerostin domain containing 1	2.9
<i>TCF2</i>	transcription factor 2, hepatic; LF-B3; variant hepatic nuclear factor	2.1
<i>TCF4</i>	transcription factor 4	2.5
<i>TCF7L1</i>	transcription factor 7-like 1 (T-cell specific, HMG-box)	1.8
<i>TCF7L2</i>	Transcription factor 7-like 2 (T-cell specific, HMG-box)	1.7
<i>TIAM1</i>	T-cell lymphoma invasion and metastasis 1	2.4

Supplementary Table 2 (page 4)

<i>TLE3</i>	transducin-like enhancer of split 3 (E(sp1) homolog, Drosophila)	1.6
<i>TLE4</i>	transducin-like enhancer of split 4 (E(sp1) homolog, Drosophila)	1.6
<i>VEGFC</i>	vascular endothelial growth factor C	1.5
<i>WNT2B</i>	wingless-type MMTV integration site family, member 2B	2.6
<i>WNT5B</i>	wingless-type MMTV integration site family, member 5B	1.9
<i>WNT9A</i>	Wingless-type MMTV integration site family, member 9A	1.6
<i>ZNF467</i>	zinc finger protein 467	1.7
<i>ZNF521</i>	zinc finger protein 521	1.7

**Expressed in normal mucosa and unchanged in adenomas**

<i>AES</i>	amino-terminal enhancer of split	
<i>ATOH1</i>	atonal homolog 1 (Drosophila)	
<i>AXIN1</i>	axin 1	
<i>AXUD1</i>	AXIN1 up-regulated 1	
<i>BCL9</i>	B-cell CLL/lymphoma 9	
<i>BGLAP</i>	bone gamma-carboxyglutamate (gla) protein (osteocalcin)	
<i>BTRC</i>	beta-transducin repeat containing	
<i>C9orf126</i>	Chromosome 9 open reading frame 126	
<i>CD24</i>	CD24 molecule	
<i>CDH1</i>	cadherin 1, type 1, E-cadherin (epithelial)	
<i>CSNK1A1</i>	Casein kinase 1, alpha 1	
<i>CSNK1D</i>	casein kinase 1, delta	
<i>CSNK1G1</i>	casein kinase 1, gamma 1	
<i>CSNK1G2</i>	casein kinase 1, gamma 2	
<i>CSNK1G3</i>	casein kinase 1, gamma 3	
<i>CSNK2A1</i>	casein kinase 2, alpha 1 polypeptide	
<i>CTBP1</i>	C-terminal binding protein 1	
<i>CTBP2</i>	C-terminal binding protein 2	
<i>CTGF</i>	connective tissue growth factor	
<i>CTNNB1</i>	catenin (cadherin-associated protein), beta 1, 88kDa	
<i>CTNNBIP1</i>	catenin, beta interacting protein 1	
<i>CYR61</i>	cysteine-rich, angiogenic inducer, 61	
<i>DIXDC1</i>	DIX domain containing 1	
<i>DLL1</i>	delta-like 1 (Drosophila)	
<i>DLL4</i>	delta-like 4 (Drosophila)	
<i>DVL1</i>	dishevelled, dsh homolog 1 (Drosophila)	
<i>DVL2</i>	dishevelled, dsh homolog 2 (Drosophila)	
<i>DVL3</i>	dishevelled, dsh homolog 3 (Drosophila)	
<i>EDN1</i>	endothelin 1	
<i>EDNRA</i>	endothelin receptor type A	
<i>EFNA3</i>	ephrin-A3	
<i>EFNA4</i>	ephrin-A4	
<i>EFNB1</i>	ephrin-B1	
<i>EFNB2</i>	ephrin-B2	
<i>EP300</i>	E1A binding protein p300	
<i>EPHA4</i>	EPH receptor A4	
<i>EPHA5</i>	EPH receptor A5	
<i>EPHB1</i>	EPH receptor B1	
<i>FBXW11</i>	F-box and WD-40 domain protein 11	

Supplementary Table 2 (page 5)

FBXW2	F-box and WD-40 domain protein 2
FBXW4	F-box and WD-40 domain protein 4
FGF4	fibroblast growth factor 4 (Kaposi sarcoma oncogene)
FOS	v-fos FBJ murine osteosarcoma viral oncogene homolog
FRAT1	frequently rearranged in advanced T-cell lymphomas
FRAT2	frequently rearranged in advanced T-cell lymphomas 2
FZD2	frizzled homolog 2 (Drosophila)
GJA1	gap junction protein, alpha 1, 43kDa (connexin 43)
GPR135	G protein-coupled receptor 135
GSK3A	glycogen synthase kinase 3 alpha
HSPG2	heparan sulfate proteoglycan 2 (perlecan)
ID2	inhibitor of DNA binding 2, dominant negative helix-loop-helix protein
ING1	inhibitor of growth family, member 1
JUN	v-jun sarcoma virus 17 oncogene homolog (avian)
JUP	junction plakoglobin
KREMEN1	kringle containing transmembrane protein 1
KRTHB6	keratin, hair, basic, 6 (monilethrix)
LDLR	low density lipoprotein receptor (familial hypercholesterolemia)
LOC642558	similar to FUS interacting protein (serine-arginine rich) 1
LRP5	low density lipoprotein receptor-related protein 5
LRP6	low density lipoprotein receptor-related protein 6
MAPK9	mitogen-activated protein kinase 9
MAPRE1	microtubule-associated protein, RP/EB family, member 1
MARK4	MAP/microtubule affinity-regulating kinase 4
MYCBP	c-myc binding protein
NFE2L2	nuclear factor (erythroid-derived 2)-like 2
OVOL1	ovo-like 1(Drosophila)
PAFAH1B1	platelet-activating factor acetylhydrolase, isoform Ib, alpha sub.45kDa
PLA2G2A	phospholipase A2, group IIA (platelets, synovial fluid)
PLAU	plasminogen activator, urokinase
PLAUR	plasminogen activator, urokinase receptor
PORCN	porcupine homolog (Drosophila)
PPARG	peroxisome proliferative activated receptor, gamma
PPP2CA	protein phosphatase 2, catalytic subunit, alpha isoform
PPP2R1A	protein phosphatase 2, regulatory subunit A (PR 65), alpha isoform
PPP2R1B	protein phosphatase 2, regulatory subunit A (PR 65), beta isoform
PPP2R5C	protein phosphatase 2, regulatory subunit B (B56), gamma isoform
PPP2R5E	protein phosphatase 2, regulatory subunit B (B56), epsilon isoform
PRKCA	protein kinase C, alpha
PRKCG	protein kinase C, gamma
PRKCI	protein kinase C, iota
PRKCQ	protein kinase C, theta
PRKD1	protein kinase D1
PTGS2	prostaglandin-endoperoxide synthase 2
PYGO2	pygopus homolog 2 (Drosophila)
RAC1	ras-related C3 botulinum toxin substrate 1 (rho family)
RHOV	ras homolog gene family, member V
RNF4	ring finger protein 4

Supplementary Table 2 (page 6)

SEC23B	Sec23 homolog B ( <i>S. cerevisiae</i> )
SEMA3C	semaphorin 3C
SEN2	SUMO1/sentrin/SMT3 specific peptidase 2
SMAD2	SMAD, mothers against DPP homolog 2 ( <i>Drosophila</i> )
SMAD5	SMAD, mothers against DPP homolog 5 ( <i>Drosophila</i> )
SMAD7	SMAD, mothers against DPP homolog 7 ( <i>Drosophila</i> )
SMO	smoothened homolog ( <i>Drosophila</i> )
STRA6	stimulated by retinoic acid gene 6 homolog (mouse)
T	T, brachyury homolog (mouse)
TCF1	transcription factor 1, hepatic; LF-B1, hepatic nuclear factor (HNF1)
TLE2	transducin-like enhancer of split 2 (E(sp1) homolog, <i>Drosophila</i> )
TNFSF11	tumor necrosis factor (ligand) superfamily, member 11
TWIST1	twist homolog 1 (acrocephalosyndactyl 3; Saethre-Chotzen synd.)
UBXD1	UBX domain containing 1
UBXD2	UBX domain containing 2
UBXD3	UBX domain containing 3
UBXD4	UBX domain containing 4
USP33	ubiquitin specific peptidase 33
VEGF	vascular endothelial growth factor
VEGFB	vascular endothelial growth factor B
WNT6	wingless-type MMTV integration site family, member 6
ZNF651	zinc finger protein 651

**Not expressed in both normal mucosa and adenomas**

CDX4	caudal type homeobox transcription factor 4
CSNK1A1	Casein kinase 1, alpha 1
CX40.1	connexin40.1
DKK1	dickkopf homolog 1 ( <i>Xenopus laevis</i> )
DKK2	dickkopf homolog 2 ( <i>Xenopus laevis</i> )
DKK4	dickkopf homolog 4 ( <i>Xenopus laevis</i> )
DKKL1	dickkopf-like 1 (soggy)
DLK1	delta-like 1 homolog ( <i>Drosophila</i> )
DLL3	delta-like 3 ( <i>Drosophila</i> )
EDN2	endothelin 2
EFNA2	ephrin-A2
EFNB3	ephrin-B3
ELAC1	ElaC homolog 1 ( <i>E. coli</i> )
EN1	engrailed homolog 1
EN2	engrailed homolog 2
EPHA6	EPH receptor A6
FGF20	fibroblast growth factor 20
FLJ14712	hypothetical protein FLJ14712
FLJ90166	hypothetical protein FLJ90166
FOSB	FBJ murine osteosarcoma viral oncogene homolog B
FOXP1	forkhead box N1
FSHB	follicle stimulating hormone, beta polypeptide
FST	follicle stimulating hormone, beta polypeptide
FZD10	frizzled homolog 10 ( <i>Drosophila</i> )
FZD9	frizzled homolog 9 ( <i>Drosophila</i> )

Supplementary Table 2 (page 7)

<b>GAST</b>	gastrin
<b>GJA10</b>	gap junction protein, alpha 10, 59kDa
<b>GJB6</b>	gap junction protein, beta 6 (connexin 30)
<b>IGF2</b>	insulin-like growth factor 2 (somatomedin A)
<b>IL6</b>	interleukin 6 (interferon, beta 2)
<b>KREMEN2</b>	kringle containing transmembrane protein 2
<b>KRTAP2-1</b>	keratin associated protein 2-1
<b>LOC391241</b>	similar to Soggy-1 protein precursor (SGY-1)
<b>LOC541472</b>	hypothetical LOC541472
<b>LOC641518</b>	hypothetical protein LOC641518
<b>LOC644985</b>	Hypothetical protein LOC644985
<b>MMP26</b>	matrix metalloproteinase 26
<b>NEUROG1</b>	neurogenin 1
<b>NEUROG3</b>	neurogenin 3
<b>NKD1</b>	naked cuticle homolog 1 (Drosophila)
<b>NRCAM</b>	neuronal cell adhesion molecule
<b>PTTG2</b>	pituitary tumor-transforming 2
<b>RUNX2</b>	runt-related transcription factor 2
<b>SFRP4</b>	secreted frizzled-related protein 4
<b>SFRP5</b>	secreted frizzled-related protein 5
<b>SHFM3P1</b>	split hand/foot malformation (ectrodactyly) type 3 pseudogene 1
<b>SIX3</b>	sine oculis homeobox homolog 3 (Drosophila)
<b>SOX17</b>	SRY (sex determining region Y)-box 17
<b>SOX2</b>	SRY (sex determining region Y)-box 2
<b>TLE6</b>	transducin-like enhancer of split 6 (E(sp1) homolog, Drosophila)
<b>WIF1</b>	WNT inhibitory factor 1
<b>WISP1</b>	WNT1 inducible signaling pathway protein 1
<b>WISP2</b>	WNT1 inducible signaling pathway protein 2
<b>WISP3</b>	WNT1 inducible signaling pathway protein 3
<b>WNT1</b>	wingless-type MMTV integration site family, member 1
<b>WNT10A</b>	wingless-type MMTV integration site family, member 10A
<b>WNT10B</b>	wingless-type MMTV integration site family, member 10B
<b>WNT11</b>	wingless-type MMTV integration site family, member 11
<b>WNT16</b>	wingless-type MMTV integration site family, member 16
<b>WNT3</b>	wingless-type MMTV integration site family, member 3
<b>WNT4</b>	wingless-type MMTV integration site family, member 4
<b>WNT7A</b>	wingless-type MMTV integration site family, member 7A
<b>WNT7B</b>	wingless-type MMTV integration site family, member 7B
<b>WNT8A</b>	wingless-type MMTV integration site family, member 8A
<b>WNT8B</b>	wingless-type MMTV integration site family, member 8B
<b>WNT9B</b>	wingless-type MMTV integration site family, member 9B

# Those classified as Wnt-signaling genes by R. Nusse (<http://www.stanford.edu/~rnusse/pathways/targets.html> and <http://www.stanford.edu/~rnusse/pathways/targetcomp.html>) and/or in the Gene Ontology database. Genes in red are the Wnt-signaling targets reported in Supplementary Table 4.

§ Within each category, genes are listed alphabetically by symbol

\* Significantly overexpressed (Up) or underexpressed (Down) in adenomas (vs. normal mucosa)

**Supplementary Table 3:** A selection of genes whose expression displayed significant positive or negative correlation with adenoma size, i.e., increase or decrease of the mRNA intensity logratio values (adenoma : normal tissue), respectively, from smaller to bigger adenomas \*

**Positive correlation: Increasing fold changes with increasing adenoma size**

<i>Affymetrix ID</i>	<i>Gene Symbol</i>	<i>Gene Name</i>
219189_at	<b>FBXL6</b>	F-box and leucine-rich repeat protein 6
235162_at	<b>MDM4</b>	Mdm4, transformed 3T3 cell double minute 4, p53 binding protein
32062_at	<b>LRRC14</b>	leucine rich repeat containing 14
200821_at	<b>LAMP2</b>	lysosomal-associated membrane protein 2
227080_at	<b>ZNF697</b>	zinc finger protein 697
206752_s_at	<b>DFFB</b>	DNA fragmentation factor, 40kDa, beta polypept. (caspase-activated DNase)
226334_s_at	<b>AHSA2</b>	AHA1, activator of heat shock 90kDa protein ATPase homolog 2
228150_at	<b>LZTR2</b>	leucine zipper transcription regulator 2
203140_at	<b>BCL6</b>	B-cell CLL/lymphoma 6 (zinc finger protein 51)
222557_at	<b>STMN3</b>	stathmin-like 3
226125_at	<b>SLC9A3</b>	solute carrier family 9 (sodium/hydrogen exchanger), member 3
201149_s_at	<b>TIMP3</b>	TIMP metalloproteinase inhibitor 3 (Sorsby fundus dystrophy)
1557580_at	<b>CABIN1</b>	Calcineurin binding protein 1
230097_at	<b>GART</b>	Phosphoribosylglycinamide formyltransferase
219359_at	<b>ATHL1</b>	ATH1, acid trehalase-like 1 (yeast)
1555259_at	<b>ZAK</b>	sterile alpha motif and leucine zipper containing kinase AZK
232201_at	<b>NKD2</b>	naked cuticle homolog 2 (Drosophila)
221499_s_at	<b>STX16</b>	syntaxin 16
224566_at	<b>TncRNA</b>	trophoblast-derived noncoding RNA
238449_at	<b>LOC440345</b>	hypothetical protein LOC440345
241815_at	<b>EST</b>	transcribed locus, hypothetical protein XP_498467 [Homo sapiens]
230494_at	<b>EST</b>	EST
229390_at	<b>RP1-93H18.5</b>	hypothetical protein LOC441168
232052_at	<b>LOC440944</b>	hypothetical gene supported by AK128398
1563088_a_at	<b>LOC284837</b>	hypothetical protein LOC284837
232052_at	<b>LOC440944</b>	Hypothetical gene supported by AK128398

**Negative correlation: Decreasing fold changes with increasing adenoma size**

216288_at	<b>CYSLTR1</b>	cysteinyl leukotriene receptor 1
37226_at	<b>BNIP1</b>	BCL2/adenovirus E1B 19kDa interacting protein 1
222377_at	<b>TBX10</b>	T-box 10
228962_at	<b>PDE4D</b>	phosphodiesterase 4D, cAMP-specific
229053_at	<b>SYT17</b>	synaptotagmin XVII
230360_at	<b>GLDN</b>	gliomedin
234709_at	<b>CAPN13</b>	calpain 13
239272_at	<b>MMP28</b>	matrix metalloproteinase 28
230360_at	<b>TMEM61</b>	transmembrane protein 61
223969_s_at	<b>RETNLB</b>	resistin like beta
212741_at	<b>MAOA</b>	monoamine oxidase A
240106_at	<b>GNPTAB</b>	N-acetylglucosamine-1-phosphate transferase, alpha and beta subunits
225822_at	<b>TMEM125</b>	transmembrane protein 125
213148_at	<b>LOC257407</b>	hypothetical protein LOC257407
229064_s_at	<b>EST</b>	EST

\* These genes were selected from the list of top 500 probes with the highest loading scores along the CCA axis 1 (see Figure 2). Selection criteria were based on the statistical relation between expression change and adenoma size (i.e., how expression change related to adenoma size).

Supplementary Figure 3, Sabates-Bellver et al.

**Supplementary Figure 3. *KIAA1199* messenger RNA expression in colorectal adenomas.** (A) *KIAA1199* mRNA levels detected in samples of normal colorectal mucosa and adenomas with the Affymetrix U133 Plus 2.0 array based on normalized raw signal values (y-axis). Levels in adenomas were 54.8 times higher than those found in the normal mucosa. This difference was highly significant ( $p < 0.0001$ ; bars: confidence intervals). (B) Real-time RT-PCR amplification of the coding region of *KIAA1199* and the control housekeeping gene *GAPDH* in two representative adenomas and matched samples of normal mucosa. (A total of 15 tissue pairs were examined in triplicate, including five collected after the present study was completed.) Ct (threshold cycle): number of cycles (x-axis) at the beginning of the log phase of amplification. After 35 cycles of PCR, *KIAA1199* was amplified in adenomas but not in the corresponding normal mucosa. At 40 cycles, a PCR product was also detected in many samples of normal mucosa (data not shown). (C) The *KIAA1199* amplification products were subjected to agarose-gel electrophoresis to verify the specificity of the amplification. M: 50-bp ladder marker; Co: negative control; NM: normal mucosa; Ad: adenoma.

**Supplementary Table 4: Genes known to be targets of Wnt/ $\beta$ -catenin signaling #**

<b>Gene Symbol</b>	<b>Gene Name</b>	<b>Ref.</b>
<b>ABCB1 (MDR1)</b>	ATP-binding cassette, sub-family B (MDR/TAP), member 1	*
<b>APCDD1</b>	adenomatosis polyposis coli down-regulated 1	1
<b>ASCL2</b>	achaete-scute complex-like 2 (Drosophila)	2
<b>ATOH1 (Hath1)</b>	Homo sapiens atonal homolog 1 (Drosophila) (ATOH1), mRNA.	*
<b>AXIN2</b>	axin 2 (conductin, axil)	*
<b>BGLAP</b>	bone gamma-carboxyglutamate (gla) protein (osteocalcin)	*
<b>BIRC5</b>	baculoviral IAP repeat-containing 5 (survivin)	*
<b>BMP4</b>	bone morphogenetic protein 4	*
<b>BTRC</b>	beta-transducin repeat containing	*
<b>CCND1</b>	cyclin D1 (PRAD1: parathyroid adenomatosis 1)	*
<b>CD24</b>	CD24 antigen (small cell lung carcinoma cluster 4 antigen)	3
<b>CD44</b>	CD44 antigen (homing function and Indian blood group system)	*
<b>CDH1</b>	cadherin 1, type 1, E-cadherin (epithelial)	*
<b>CDX4</b>	caudal type homeo box transcription factor 4	*
<b>CLDN1</b>	claudin 1	*
<b>CSPG2</b>	chondroitin sulfate proteoglycan 2 (versican)	*
<b>CST1</b>	cystatin SN	4
<b>CTGF</b>	connective tissue growth factor	*
<b>CYR61</b>	cysteine-rich, angiogenic inducer, 61	*
<b>DKK1</b>	dickkopf homolog 1 (Xenopus laevis)	*
<b>DLL1</b>	delta-like 1 (Drosophila)	*
<b>DRCTNNB1A</b>	down-regulated by Ctnnb1, a	5
<b>EDA</b>	ectodysplasin A	*
<b>EDAR</b>	ectodysplasin 1, anhidrotic receptor	*
<b>EDN1</b>	endothelin 1	*
<b>EDN3</b>	endothelin 3	4
<b>EFNB1</b>	ephrin-B1	*
<b>EGFR</b>	epidermal growth factor receptor	*
<b>EMP1</b>	epithelial membrane protein 1	*
<b>EN2</b>	engrailed homolog 2	*
<b>ENPP2</b>	ectonucleotide pyrophosphatase/phosphodiesterase 2 (autotaxin)	*
<b>EPHB2</b>	EPH receptor B2	*
<b>EPHB3</b>	EPH receptor B3	*

**Supplementary Figure 4.**  
**Degree of co-expression**  
**between *KIAA1199* and**  
**known Wnt target genes.**

(A) 4307 genes (6379 probes) were significantly up-regulated in adenomas, compared with normal mucosa (no fold-change restriction). This set included 39 of the 110 known Wnt target genes listed in Supplementary Table 4 and 357 genes whose expression appeared to be co-regulated with that of *KIAA1199* (Pearson correlation value of  $\geq 0.8$ ). Comparison of these two subsets revealed that 49% (19/39) of the known Wnt target genes that were significantly over-expressed in our adenomas also displayed positive correlation with *KIAA1199* expression (panel B and Figure 3A and 3B). In contrast, co-regulation with *KIAA1199* was much less common among the upregulated genes that are not currently considered to be Wnt targets (338/4268, 7.9%) (Fisher exact test;  $p < 0.0001$ ).

**Background & Aims:** In colorectal cancer, activating mutations in the Wnt pathway transform epithelial cells through the inappropriate expression of a TCF4 target gene program, which is physiologically expressed in intestinal crypts. **Methods:** We have now performed an exhaustive array-based analysis of this target gene program in colorectal cancer cell lines carrying an inducible block of the Wnt cascade. Independently, differential gene-expression profiles of human adenomas and adenocarcinomas vs normal colonic epithelium were obtained. **Results:** Expression analyses of approximately 80 genes common between these data sets were performed in a murine adenoma model. The combined data sets describe a core target gene program, the intestinal Wnt/TCF signature gene set, which is responsible for the transformation of human intestinal epithelial cells. **Conclusions:** The genes were invariably expressed in adenomas, yet could be subdivided into 3 modules, based on expression in distinct crypt compartments. A module of 17 genes was specifically expressed at the position of the crypt stem cell.

The overwhelming majority of colorectal cancers (CRCs) is initiated by activating mutations in the Wnt pathway.<sup>1,2</sup> These mutations either remove the tumor suppressors adenomatous polyposis coli (APC), or axin or activate the proto-oncogene  $\beta$ -catenin. As a common result,  $\beta$ -catenin accumulates in the nucleus, and constitutively binds to the T-cell factor (TCF)4 transcription factor, resulting in transcriptional activation of Wnt/TCF4 target genes, initiating transformation of intestinal epithelial cells.<sup>3,4</sup> Physiologically, the Wnt pathway is essential for the maintenance of crypt progenitor compartments, as evidenced by mice lacking the TCF4 transcription factor,<sup>5</sup> or transgenically expressing the secreted Dickkopf-1 Wnt inhibitor.<sup>6,7</sup>

A multitude of reports have appeared in which single-candidate TCF4 target genes have been described (eg, references listed in Table 1 and available at <http://www.stanford.edu/~rnusse/pathways/targets.html>). Typically, these studies describe differential expression between cells with and without an activated Wnt pathway, fol-

lowed by transient promoter assays. DNA array technology allows the assessment of differential messenger RNA (mRNA) expression on a genome-wide scale.

### Materials and Methods

#### Cell Culture

CRC cell lines LS174T and DLD1, stably expressing inducible dominant-negative (dn)TCF1 or dnTCF4, were generated as previously described.<sup>8</sup> The Wnt pathway activity in the CRC cells was determined as described previously<sup>9</sup> using the optimized TCF reporter pTopGlow and its negative control pPopGlow, constructed in our laboratory.<sup>9</sup>

#### Oligonucleotide Microarray Analysis of CRC Cell Lines

RNA was isolated after 10 and 20 hours induction of the dnTCFs. RNA quality was assessed using capillary gel electrophoresis (BioAnalyzer; Agilent Technologies). Complementary DNA (cDNA) synthesis and labeling was performed according to Affymetrix (Santa Clara, CA) guidelines. cRNA was synthesized and labeled with Affymetrix One-cycle Target Labeling kit, and hybridized on Affymetrix GeneChip HG-U133 plus 2.0 microarrays. The overall fluorescence for each GeneChip was scaled to a target intensity of 200. The expression profiles at 10 and 20 hours after induction were compared with those of noninduced controls by pair-wise comparisons performed with GeneChip Operating Software (Affymetrix). Only probes with a significantly decreased call for both time points were included.

#### Oligonucleotide Microarray Analysis of Human Tissues

Colorectal adenomas were collected during endoscopy at a single gastroenterology unit (Belcolle Hospital, Viterbo, Italy) with full institutional review board approval. In each patient, normal mucosa also was collected at about a 2–4-cm distance from the adenoma. Biopsy specimens

**Abbreviations used in this paper:** APC, adenomatous polyposis coli; CRC, colorectal cancer; dn, dominant-negative; TCF, T-cell factor; wt, wild type.

NOTE. Fold changes of genes down-regulated in all 4 CRC cell lines on over expression of dnTCFs are shown.

<sup>a</sup>Genes also have been identified in the Stanford array experiment.<sup>8</sup>

were immersed immediately in RNAlater (Ambion, Huntingdon, UK), homogenized, and RNA was extracted with RNeasy kit (QIAGEN, Basel, Switzerland). RNA quality was verified by capillary gel electrophoresis and a total of 32 pairs of normal mucosa and adenomas was analyzed. cRNA was synthesized, labeled, and hybridized as described earlier. GeneSpring software (Silicon Genetics, Redwood City, CA) was used for gene expression data and statistical analyses. The nonparametric Mann-Whitney test was used with a false discovery rate of .05 and Bonferroni correction for the group comparison analysis (normal mucosa vs adenomas or cancer). Transcriptome data from a series of 25 previously collected colon adenocarcinomas and 10 samples of normal mucosa from some of these patients were obtained with the same procedure<sup>10</sup> and used in this study.

### In Situ Hybridizations

Mouse orthologs of selected transcripts were obtained as expressed sequence tags IMAGE consortium (MRC geneservice, Badrahan, UK) or RZPD (German Resource Center for Genome Research, Berlin, Germany). These clones were used for in vitro transcription reactions to generate probes for in situ hybridizations. Protocols for in vitro transcription and in situ hybridizations are described elsewhere.<sup>11</sup>

## Results

### Inhibition of the Constitutively Active Wnt Pathway in CRC Cells

N-terminally truncated TCFs do not bind  $\beta$ -catenin and act as potent inhibitors of endogenous  $\beta$ -catenin/TCF complexes.<sup>12</sup> Tcf4 is expressed physiologically in the intestine.<sup>13</sup> In our hands, the DNA-binding characteristics of

TCF4 and TCF1 are essentially identical. For TCF target gene identification, we generated a panel of cell clones from the CRC cell lines LS174T (mutationally activated allele of the *CTNNB1* gene encoding  $\beta$ -catenin) and in DLD1 (mutant APC), in which the Wnt cascade could be inhibited by inducible expression of either dnTCF1 or dnTCF4. Individ-

**Figure 1.** Over expression of dnTCFs inhibits the Wnt pathway in CRC cells. TCF/ $\beta$ -catenin driven transcription is abrogated by over expression of dnTCF1 or dnTCF4 in (A) LS174T cells and (B) DLD1 cells. The activity of the TCF reporter, pTopGlow (□, TOP), and the control, pPopGlow (■, FOP), after 20 hours with or without doxycycline treatment is shown. Parental cells that expressed the tetracycline repressor (TR) were used as controls. Renilla luciferase levels were used as transfection controls. (C) Venn diagram showing the (overlapping) down-regulated probes on dnTCF1 or dnTCF4 induction. Selection is based on down-regulation in 2 or more of the 4 cell-line transfectants used in this study. Not shown in the figure is the overlap in 6 unique probes between LS174T/dnTCF1 and DLD1/dnTCF4 and 6 probes between LS174T/dnTCF4 and DLD1/dnTCF1.

**Figure 2.** The intestinal Wnt/TCF signature gene set. TCF/ $\beta$ -catenin target genes were selected by comparing the 387 probes (lower circle) obtained with the procedure described in Figure 1C with the 8307 probes whose expression levels in human tumors were increased significantly, relative to those in normal mucosa. The left upper circle represents 3319 probes increased in adenomas, whereas the right upper circle represents 4988 probes increased in carcinomas (1971 were increased in both tumor types). With this approach, we classified 51 genes (71 probes) up-regulated in adenomas, 36 genes (40 probes) up-regulated in carcinomas, and 121 genes (144 probes) up-regulated in both tumor types as  $\beta$ -catenin/TCF target genes. These gene lists are reported in Supplementary Table 1 (supplementary material online at [www.gastrojournal.org](http://www.gastrojournal.org)).

ual transfectants were selected based on the induced inhibition of the constitutive Wnt activity. For the 4 selected clones, the constitutively active Wnt pathway could be inhibited close to background levels on doxycycline-mediated induction of dnTCF1 or dnTCF4 (Figure 1A and B). Moreover, all clones underwent a rapid, robust G1 arrest within 24 hours (not shown).

#### The Genetic Program Driven by $\beta$ -Catenin/TCF in CRC Cell Lines

We originally subjected the LS174T/dnTCF4 clone to a microarray experiment on the Stanford spotted-cDNA array platform containing 24,000 probes.<sup>8</sup> To obtain a more comprehensive list of TCF target genes in intestinal cancer cells, we performed expression profiling using the Affymetrix GeneChip HG-U133 plus 2.0, which contains 54,675 probes. We initiated analyses with the LS174T/dnTCF4 cells. mRNA was isolated at 10 and 20 hours after induction and from noninduced control cells. The 115 probes reported on the Stanford platform<sup>8</sup> represented 101 significantly down-regulated genes, all of which also were present on the Affymetrix arrays. More than 60% of these 101 genes turned out to be down-regulated significantly at either the 10- or 20-hour time points in the Affymetrix measurements, whereas 26% were significantly down-regulated at both time points. This showed good reproducibility and robustness of the assay, given the extensive differences in technology between the 2 platforms.

Similar array experiments then were performed for the other 3 transfectants (LS174T/dnTCF1, DLD1/dnTCF4, and DLD1/dnTCF1). For each cell line, we compiled lists of probe features significantly down-regulated at both time points. Figure 1C gives a Venn diagram summarizing the down-regulated features shared between the 4 different cell

**Figure 3.** Confirmation and classification of TCF target genes by in situ hybridization on intestines of adult *APC<sup>Mm</sup>* mice. All Wnt signature genes tested were expressed in (A, C, E, and G) wild type crypts and in (B, D, F, and H) adenomas of *APC<sup>Mm</sup>* mice. The staining patterns in wt crypts could be divided into 3 categories. (A and B) An example of the expression of a gene within the first category, the mouse ortholog of *HSPC111*, is shown. In addition to expression within the proliferative compartment of crypts and adenomas, a decreasing gradient of signal is observed along the base of the villus. (C and D) Another gene in this category, the mouse ortholog for *NOL1*, showed expression restricted to the proliferative compartment of crypts and adenomas, but lacked significant expression along the villus. (E and F) The second staining pattern involves the Paneth cells at the bottom of the crypts, as represented by the mouse ortholog for *MMP7*. (G and H) In situ hybridizations for the mouse ortholog of *ASCL2* defined a third category that revealed expression in adenomas and in a few cells near the crypt bottom. This position coincides with the location of the elusive crypt stem cells. Size bars represent 50  $\mu$ m, and adenomas are circled by dotted lines.

lines. The 15 genes down-regulated in all 4 cell lines are reported in Table 1. Table 1 includes some well-known Wnt targets *AXIN2*,<sup>14–16</sup> *c-Myc*,<sup>17</sup> *ASCL2*,<sup>18</sup> *LGR5*,<sup>19</sup> *HIG2*,<sup>20</sup> *BMP4*,<sup>21</sup> and *SOX4*,<sup>22</sup> as well as 8 novel TCF target genes.

To obtain an information-rich, yet robust data set, we arbitrarily selected the probes that were down-regulated at both time points in at least 2 different cell lines. This resulted in a list that contained 387 probe features. This list was used for comparison with the gene-expression profiles of adenomas and adenocarcinomas described later.

### Gene Expression Profiles of Human Adenomas and Adenocarcinomas

The transcriptome of 32 adenomas and 25 carcinomas was analyzed and compared with that of normal colonic mucosa. The genes up-regulated in adenomas and/or carcinomas were compared with those of the 387  $\beta$ -catenin/TCF responsive genes identified in the dnTCF CRC cell lines. Figure 2 shows the Venn diagram procedure we used to select the Wnt/TCF signature gene set. A total of 255 common probes corresponding to 208 different genes are reported in Supplemental Table 1 (supplementary material online at [www.gastrojournal.org](http://www.gastrojournal.org)). A total of 121 of the genes were up-regulated in both tumor types, whereas 51 and 36 were up-regulated only in the adenomas or in carcinomas, respectively.

### Confirmation of Target Genes by In Situ Hybridizations

In our initial study,<sup>8</sup> we observed that, as a rule, the identified TCF target genes were expressed physiologically in rapidly dividing crypt cells. It since has been observed that a subset of TCF target genes is expressed in the postmitotic Paneth cells, which are located at the crypt bottom.<sup>23,24</sup> We extended these observations for the intestinal Wnt/TCF signature gene set by in situ hybridizations on intestinal tissue derived from adult mice carrying the *Apc<sup>min</sup>* allele.<sup>25</sup> In situ hybridizations were performed for approximately 80 genes (Figure 3 and Supplemental Table 2; supplementary material online at [www.gastrojournal.org](http://www.gastrojournal.org)). All tested genes were expressed in the *Apc<sup>min</sup>* adenomas. The staining patterns in crypts could be grouped in several categories.

The first category consisted of about 80% of the tested genes. These genes were expressed in the proliferative compartment of the crypts. Examples are given in Figure 3A–D.

The second category of TCF target genes comprised the Paneth cell maturation markers.<sup>23,24</sup> The tyrosine kinase receptor EphB3, present in our Wnt/TCF signature gene set, falls in this category.<sup>26</sup> Other Paneth cell-specific genes such as *MMP7* (Figure 3E and F) and defensin-6 are not represented in the signature because they were not expressed in the cell lines. They were, however, clearly up-regulated in the tumor samples in the current study.

A third category (17 genes; Supplementary Table 2) yielded staining in 1–5 crypt cells, typically located near the

crypt bottom. The cells were distinct from the Paneth cells. The location was highly reminiscent of the position to which the elusive crypt stem cells have been mapped.<sup>27,28</sup> As an example, the expression of the mouse ortholog of *ASCL2* is given in Figure 3G and H. Of note, a previously published intestinal stem cell marker, *Musashi*,<sup>29,30</sup> in our hands (data not shown) would be best classified in our first category.

## Discussion

The current study builds on previous cell line-based work from our laboratory.<sup>8</sup> Here, we provide a comprehensive identification of TCF4 targets in 2 different cell lines carrying 2 different dnTCF genes, and by performing differential gene-expression analysis on a genome-wide oligonucleotide array platform. Moreover, we relate these findings to expression profiles of a set of human adenomas and adenocarcinomas. The Wnt/TCF signature gene set defines the core program activated by TCF4 in intestinal epithelial cells. Because the CRC cell lines used in this study arrest in the G1 phase of the cell cycle on inhibition of the Wnt cascade, this program is essential for the proliferative capacity of CRC cell lines in culture. These observations can be extrapolated to human intestinal tumors, in that the shared TCF4 target gene program likely represents the primary driver behind the transformation behavior of these transformed lesions. Moreover, the individual genes within the signature represent promising targets for therapy of CRC because their expression consistently is activated as the direct result of oncogenic Wnt pathway mutations, although many target genes will be involved causally in the transformed behavior of the neoplastic cells.

The TCF4 target gene program as activated in colorectal neoplasia consists of at least 3 distinct modules, as revealed by studies of physiologic gene expression in murine small intestinal crypts. Genes within one of the modules are expressed by the rapidly dividing crypt progenitors of the transit-amplifying compartment, and are likely the driving force behind the proliferative activity of intestinal neoplasia and cell lines derived thereof. Another module is correlated with maturation of postmitotic Paneth cells, as previously described.<sup>24</sup> We believe that the expression of the Paneth cell module in intestinal neoplasia is fortuitous and does not contribute to malignant transformation.

The discovery of a module expressed at the stem cell position was unexpected. Genes within this module may serve as starting points to study intestinal stem cell biology. A role for Wnt signaling in the biology of the transient-amplifying compartment of crypts has been firmly established previously.<sup>5–7</sup> A similar role in the biology of the intestinal stem cell has so far remained speculative.<sup>31</sup> The TCF target genes in the stem cell module may solidly link physiologic Wnt signaling to intestinal stem cell biology.

Wnt signature genes tested with *in situ* hybridizations were expressed in wt crypts and in adenomas of *Apc<sup>min</sup>* mice. The staining patterns in crypts could be divided into three categories. Genes within module 1 are expressed by the rapidly dividing crypt progenitors of the transit amplifying compartment. Module 2 is correlated with maturation of post-mitotic Paneth cells. Module 3 consists out of the target genes expressed at the stem cell position in the crypts.

**Background & Aims:** Colon cancers with defective DNA mismatch repair (MMR) have peculiar molecular, pathologic, and clinical features, including high-level microsatellite instability, conspicuous lymphocytic infiltration, preferential location in the proximal colon, and better prognosis. Our aim was to characterize the transcriptional profile of this colon cancer subset. **Methods:** An oligonucleotide microarray containing 12,625 probes was used to evaluate gene expression in 25 proximal colon cancers, 10 samples of normal colon mucosa, and 14 colon cancer cell lines. Transcriptional profiles of MMR-deficient cancers and cell lines were compared with those of their MMR-proficient counterparts. **Results:** Unsupervised analysis of microarray data showed that MMR status exerts a predominant influence on the gene expression profile of proximal colon cancers. Hierarchical clustering divided the cancers into 2 groups corresponding almost perfectly with their MMR status. Supervised analysis identified numerous gene expression changes that represent a genetic signature of MMR-deficient colon cancers. Changes in genes involved in apoptosis and the immune response were consistent with the better prognosis of MMR-deficient cancers. In MMR-deficient cancers and cell lines, *4-1BBL*, a crucial gene in the anti-tumor immune response, was, respectively, 2.4 and 6.0 times more expressed than in their MMR-proficient counterparts. This difference was confirmed by quantitative reverse-transcription polymerase chain reaction and flow cytometric assessment of 4-1BBL protein expression in colon cancer cell lines. Our analysis also showed novel possible gene targets of microsatellite instability. **Conclusions:** MMR inactivation produces distinct changes in the cellular messenger RNA pool, which is consistent with a unique tumorigenesis pathway.

mispairs and strand misalignments that occur during DNA replication.<sup>3,4</sup> MMR-deficient cells are phenotypically characterized by microsatellite instability (MSI), widespread genetic instability involving mononucleotide and dinucleotide repeats.<sup>5</sup> Its tumorigenic relevance is supported by evidence that malignant transformation may depend on frameshift mutations within microsatellites in the coding region of tumor suppressor genes.<sup>6,7</sup> Compared with their MMR-proficient counterparts, MMR-deficient colon cancers are more frequent in the proximal colon and more likely to be near diploid, poorly differentiated, and mucinous. They also have lower rates of lymph node metastasis and a better overall prognosis, which is believed to depend in part on their seemingly enhanced immunogenicity reflected by conspicuous intraepithelial T-lymphocyte infiltrations and nodular B-cell aggregation.<sup>8-10</sup> It is now accepted that MMR-deficient colon cancers arise through a distinct transformation process. Our objective was to identify the transcriptional features that distinguish these cancers from those in which the MMR system is fully functional.

#### Materials and Methods

We analyzed 25 primary proximal colon cancers (12 MMR deficient and 13 MMR proficient) (Table 1), 10 specimens of normal proximal colon mucosa (from 5 of the 12 patients with MMR-deficient colon cancers and 5 of the 13 patients with MMR-proficient colon cancers), and 14 colon cancer epithelial cell lines (7 MMR deficient and 7 MMR proficient) (Table 2). The MMR status of the cancers was determined by immunohistochemical assessment of *MSH2*,

Mismatch repair (MMR)-deficient colorectal cancers are associated with inherited<sup>1</sup> and somatic<sup>2</sup> alterations in the *MSH2*, *MSH6*, *MLH1*, and *PMS2* genes, which are involved in the repair of DNA base-base

*Abbreviations used in this paper:* MMR, mismatch repair; MSI, microsatellite instability; UTR, untranslated region.

<sup>i</sup>Signet ring cell carcinoma.

*MSH6*, *MLH1*, and *PMS2* expression and by evaluation of MSI at BAT-26 and *bMLH1* promoter methylation, as described elsewhere.<sup>4</sup> The MMR status of the cell lines, which has been documented in previous reports, was confirmed by Western blot of the MMR proteins.<sup>11</sup>

All tissues were prospectively collected at a single hospital in Zurich, Switzerland, with full institutional review board approval. Immediately after resection, cancers were trimmed (ulcerated and necrotic tissues, adenomatous tissue margins), and the resulting specimen, representing the invasive region of the cancer, was cut into smaller pieces and stored in RNeasy (Ambion, Huntingdon, UK) for microarray analysis. The tissue adjacent to this section was fixed in buffered formalin, embedded in paraffin, and sectioned for histologic and molecular evaluation of tumor characteristics (Table 1). This area was also used to evaluate the percentage of cancerous epithelial cells in each tumor (range, 50%–85%).

Fifty milligrams of the fragments stored in RNeasy were homogenized, total RNA was extracted (Absolutely RNA kit; Stratagene, Amsterdam, The Netherlands), and RNA integrity was verified by capillary gel electrophoresis. The same procedure (excluding homogenization) was used to extract total RNA from  $5 \times 10^6$  cultured cells of each line. For each tissue or cell line specimen, 15 µg of complementary RNA, synthesized and labeled as previously described,<sup>12</sup> were analyzed with the Affymetrix U95Av2 array (Affymetrix, High Wycombe, UK), which contains in situ synthesized oligonucleotides (12,625 probes) representing approximately 10,000 unique full-length genes. Gene expression data were analyzed with unsupervised and supervised hierarchical clustering analyses and principal component analysis (see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org) and <http://www.imcr.unizh.ch/research/researchdetail.php?StaffId=11>). NOTE. COLO741 and CX1 cells were kindly provided by Ian Tomlinson (London Research Institute, England) and GP5d cells by Donna E. Davies (CRC Wessex Medical Oncology Unit, Southampton, England). The other cell lines were from the cell line repository of the Zurich Cancer Network. The primary alteration of MMR protein expression is reported in bold. *MLH1* and *MSH2* alterations lead to proteolytic degradation of PMS2 and *MSH6*, respectively. The nonexpression of *MSH2* in GP5d cells is a novel finding; all other alterations are consistent with current literature data. <sup>a</sup>Data in this column refer to methylation of the *MLH1* promoter region that is critical for *MLH1* gene silencing, that is, bases -289 to -202 upstream from the transcription start site (GeneBank no. U83845).<sup>4</sup>

<sup>b</sup>In these cell lines, the absence of methylation in the previously cited region was accompanied by methylation of another region (-716 to -563) of the promoter, which is considered to be less closely associated with gene silencing.<sup>4</sup>

<sup>c</sup>*MLH1* is mutated in HCT116.

netics, Redwood City, CA) was used for statistical analysis of microarray data. For supervised statistical group comparisons, the Mann-Whitney test was used with a false discovery rate of 0.05 and Benjamini-Hochberg multiple testing correction; for comparison of normal mucosal tissues and cancers, which yielded larger intergroup differences, the more stringent Bonferroni correction was used. Other data were analyzed with Student *t* test,  $\chi^2$  test, and Fisher exact test.

Microarray findings were confirmed by one-step real-time reverse-transcription polymerase chain reaction (as described previously<sup>12</sup>), and 4-1BBL protein expression in colon cancer cell lines was evaluated with flow cytometry (see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)).

## Results

Fifty-one proximal colon cancers were collected in 2001 and 2002. All 12 (23.5%) satisfying our criteria for MMR deficiency (see Materials and Methods) underwent microarray analysis (Table 1), along with 13 of 39 MMR-proficient cancers, the closest matches for the MMR-deficient tumors (in terms of patient age/sex, tumor stage/grade, percentage of neoplastic epithelial cells in the specimen).

Intraepithelial lymphocyte infiltration and mucin positivity were more frequent among MMR-deficient cancers. *MLH1* gene silencing accounted for the MMR deficiency in 10 of 12 MMR-deficient cancers (all spo-

radic). The mean *MLH1* transcript level in the MMR-proficient cancers was 2.2 times higher than that of the *MLH1*-deficient subset of MMR-deficient cancers ( $t = 6.34$ ;  $P < .0001$ ).

Unsupervised hierarchical clustering effectively segregated the normal mucosa and cancer specimens (Figure 1). Supervised statistical group comparison analysis then identified 182 genes with markedly different transcript levels in these 2 groups (fold differences of  $\geq 4.0$ ), suggesting their potential relevance to colon carcinogenesis in general (Supplementary Table 1, see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)). The numerous genes in this set whose association with colon cancer has not been previously documented are the subjects of another report.

Unsupervised hierarchical clustering also divided the 25 cancers into 2 groups that coincided almost perfectly with the MMR status (Figure 1). This finding was confirmed by principal component analysis of the colon cancer data. As shown in Figure 2A and B, component 1, which explained 16% of the variance in this data set, clearly discriminated between MMR-deficient and MMR-proficient cancers. Component 2, which accounted for 11% of all variance, showed no correlation with MMR status. A preliminary investigation suggests that it may be related to the lymph

**Figure 1.** Unsupervised hierarchical clustering of normal colon mucosa and colon cancer samples based on analysis with the Affymetrix gene set after exclusion of unexpressed genes (see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)). The 5858 probes plotted on the y-axis are color coded to indicate their expression levels relative to the median level for the gene across the entire sample set (blue, lower; red, higher). The 35 tissue samples represented on the x-axis include 10 normal mucosa samples (green bars), 12 MMR-deficient cancers (red bars), and 13 MMR-proficient cancers (blue bars).

node status of the cancers (Figure 2C) and the growth patterns of the cancers ("infiltrating" vs "expansive"<sup>13</sup>) (data not shown).

Next, in a supervised analysis based on the MMR status of the cancers, we identified 100 genes that were differentially expressed in MMR-deficient and MMR-proficient cancers with fold differences of  $\geq 2.0$  (Table 3). In supervised clustering analysis (Figure 3A), this gene set effectively differentiated the 2 tumor subsets and was therefore designated the MMR status signature. It re-

flects the changes in gene expression (several already identified by others<sup>14,15</sup>) most likely to explain the clinicopathologic differences between MMR-proficient and MMR-deficient colon cancers.

Our next goal was to identify the nature of these expression changes with respect to the normal mucosa and, using the procedure described in Figure 4, to differentiate alterations that are specific to MMR-deficient versus MMR-proficient colon cancers. This process identified 39 genes whose alterations are likely to contribute to tumorigenesis within a specific MMR context. Analysis of these MMR-related tumorigenesis signature genes, which appear in bold in Table 3, reveals down-regulation of 2 putative tumor suppressors (guanylate cyclase 2C,<sup>16</sup> PURA<sup>17</sup>) and up-regulation of 4 putative oncogenes (thymidylate synthase,<sup>18</sup> DUSP4,<sup>19</sup> uPAR,<sup>20</sup> COPS3<sup>21</sup>) as possible markers of MMR-deficient colon cancer tumorigenesis.

In an attempt to isolate changes occurring in the epithelial cell component of the cancers, we compared the colon cancer expression profiles with those of the 14 colon cancer epithelial cell lines. When the relation between expression levels of a gene in MMR-deficient and MMR-proficient cancers (ie, MMR-proficient expression greater than MMR-deficient expression or vice versa) was also observed in the comparison of MMR-deficient and MMR-proficient cell lines, the difference was presumed to reflect an epithelial cell-specific alteration.

Principal component analysis revealed that MMR status also had a substantial impact on the transcriptomes of the colon cancer cell lines (Figure 2D and E). Supervised statistical group comparison analysis then revealed 66 genes whose transcript levels in MMR-proficient and MMR-deficient cell lines were significantly different, with fold differences of  $\geq 2.0$  (Figure 3B and Supplementary Table 2, see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)). This set represents a cell line-related version of the MMR status signature identified for colon cancers (Table 3). However, the overlap between these 2 signatures was quite limited (the 12 genes underlined in Table 3) because both had been identified with a fold-difference cutoff of 2.0. Elimination of this cutoff expanded the overlap list to 54 genes, whose altered expression in MMR-defined subgroups of colon cancer cell lines was statistically significant and directionally identical to those observed in the cancers themselves. This set was designated the MMR-related epithelial cell signature (Table 4 and Figure 3C).

Some of the differences noted thus far might conceivably reflect transcriptional effects of MSI within the coding or regulatory regions of genes expressed by cancerous epithelial cells. This hypothesis was confirmed by

**Figure 2.** Principal component analysis of the 25 proximal colon cancers and the 14 colon cancer cell lines. (See supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org) for details on principal component analysis methodology.) (A) Normalized component-1 output values (y-axis, log-scale) for the 25 cancer specimens (x-axis, numbered as in Table 1). The difference between values for MMR-proficient and MMR-deficient cancers was highly significant ( $t = 4.70$ ;  $P < .0001$ ). (B) Unsupervised hierarchical clustering of the 25 cancers based on the component-1 gene set, that is, the 151 genes (160 probes) with significant principal component analysis values (greater than 0.7 and less than -0.7) in component 1. With 2 exceptions, MMR-proficient cancers 3 and 8 (red bars), the cancers formed 2 clusters that coincided with MMR-status subgroups. (C) Normalized component-2 output values (y-axis, log-scale) for the 25 cancers (x-axis, numbered as in Table 1). There was a highly significant difference between values for the lymph node-positive and lymph node-negative cancers ( $t = 5.27$ ;  $P < .0001$ ). (D) Component-1 and (E) component-2 output values (y-axes, log-scale) for the 14 colon cancer cell lines (x-axes). Components 1 and 2 accounted for 20% and 13%, respectively, of the total variance in the cell line data set. In both cases, MMR-deficient and MMR-proficient cell lines were distinguished by significantly different output values (component 1:  $t = 2.26$ ,  $P = .043$ ; component 2:  $t = 3.88$ ,  $P = .0022$ ).

the finding of a higher frequency of microsatellites in the complementary DNAs of the MMR-related epithelial cell signature genes (46%) compared with that (30%) of 100 randomly selected genes expressed without MMR-related variations by the cancers and cell lines (odds ratio, 2.01; 95% confidence interval, 1.01–3.99;  $P = .05$ ). The

signature genes also presented significantly longer mononucleotide repeats in the 3' untranslated regions (UTRs) of microsatellite-containing genes ( $t = 3.26$ ;  $P = .0026$ ) (Table 5). All but one of the MMR-related epithelial cell signature genes containing coding region and/or 5'-UTR mononucleotide repeats displayed decreased transcript

NOTE. Bold type indicates *MMR-related tumorigenesis signature* genes (see Figure 4). Thirty-nine genes whose altered expression (vs normal mucosa) were observed exclusively in MMR(+) OR MMR(-) colon cancers. The fold changes with respect to normal mucosa are shown in the last 2 columns.

Underlined type indicates 12 genes displaying similar patterns of differential expression [MMR(+) vs. MMR(-)] in both colon cancers and colon cancer cell lines (no fold change restriction was applied to cell lines).

C(+), MMR-proficient cancer; C(-), MMR-deficient cancer; NM, normal mucosa; MMR(+), MMR proficient; MMR(-), MMR deficient.

<sup>a</sup>Statistical significance was assessed with the Mann-Whitney test with a false discovery rate of 0.05 and Benjamini-Hochberg multiple testing correction. Minimal fold difference, 2.0: genes whose differential expression was characterized by fold differences <2.0 are not shown, even if statistically significant.

levels in MMR-deficient cells, whereas those with 3'-UTR microsatellites presented higher messenger RNA levels in these cells. The cell line expression of 3 genes from this latter group (*NUTF2*, *HNRPL*, and *CTNBN1*) was analyzed with quantitative reverse-transcription polymerase chain reaction. Their coding regions were amplified with similar efficiency in all 14 lines, but amplification of the repeat-containing 3'-UTRs was much more efficient in the MMR-deficient cell lines (Supplementary Figure 1, see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)). Moreover, in the MMR-deficient lines, the long 3'-UTR mononucleotide stretches present in these 3 genes were always several nucleotides shorter than their counterparts in the MMR-proficient lines (data not shown), suggesting that the more efficient 3'-UTR amplification was somehow related to MSI.

We then focused our analysis on *4-1BBL*, a gene involved in the antitumoral immune response. Levels of RNA for this gene in MMR-deficient cancers and cell lines were, respectively, 2.4 and 6.0 times higher than those observed in their MMR-proficient counterparts (Figure 5A). This difference was confirmed by quantitative reverse-transcription polymerase chain reaction amplification of the *4-1BBL* coding region (Figure 5B) and flow cytometric assessment of *4-1BBL* levels (Figure 5C) in colon cancer cell lines.

## Discussion

Analysis of the MMR status and MMR-related epithelial cell signatures shows several changes that might explain the better prognosis associated with MMR-deficient colon cancers. Compared with MMR-proficient cancers, MMR-deficient tumors presented reduced transcript levels of several genes with functions that presumably favor tumor progression (eg, *PTP4A3*,<sup>22</sup> *PRKCI*,<sup>23,24</sup> *VEGFB*,<sup>25</sup> *B-myb*,<sup>26</sup> *SAS*,<sup>27</sup> *SIAT1*,<sup>28</sup> *NOX1*,<sup>29</sup> *DD5*,<sup>30</sup> and *IHH*<sup>31</sup>) and increased expression of factors believed to inhibit tumor growth, progression, and/or invasiveness. The latter included the proapoptotic

**Figure 3.** Supervised hierarchical clustering of colon cancers and colon cancer cell lines classified on the basis of their MMR status. (A) Clustering of 25 colon cancers by the MMR-status signature gene set (100 genes, 106 probes) shown in Table 3. (B) Clustering of 14 colon cancer cell lines by the 66 genes shown in Supplementary Table 2, which can be considered a cell line-specific version of the MMR-status signature set. (C) Clustering of colon cancers and cell lines by the MMR-related epithelial cell signature gene set shown in Table 4. Sample tree: MMR-proficient cell lines in light blue, MMR-proficient cancers in dark blue, MMR-deficient cell lines in orange, and MMR-deficient cancers in red.

**Figure 4.** Selection of the MMR-related tumorigenesis signature gene set from the MMR-status signature gene set. (A) The light gray circle represents the 682 genes whose expression levels in MMR-deficient cancers were significantly increased or decreased, relative to those in normal mucosa (NM), with fold changes (FC) of  $\geq 2.0$ . (The 10 normal mucosa samples were considered as a homogeneous group because their variability was much less marked than that observed among the cancer specimens, as shown in Figure 1). The white circle represents 759 genes displaying significantly altered expression (no FC restrictions) in MMR-proficient cancers with respect to normal mucosa. (Elimination of the FC cutoff in this selection allowed us to identify MMR-deficient-specific changes with greater accuracy.) The intersection of the 2 circles represents the 383 genes displaying similar alterations in MMR-deficient and MMR-proficient cancers with respect to normal mucosa. Exclusion of these genes leaves 299 genes whose expression was altered (relative to normal mucosa) exclusively in MMR-deficient cancers. (B) A similar procedure was used to identify 190 genes with significant expression changes (relative to normal mucosa) that were confined exclusively to MMR-proficient cancers. (C) The light gray circles here represent the sets of 299 and 190 genes obtained in A and B, while the dark gray circle represents the 100 genes making up the MMR-status signature (Table 3). Gene set characteristics in terms of differences between transcriptional levels in MMR-deficient cancers, MMR-proficient cancers, and normal mucosa are summarized in the small rectangles; differences are classified as significant (S) or nonsignificant (NS). Overlap between the light gray circle on the left and the dark gray circle represents 21 genes whose expression levels in MMR-deficient cancers were significantly different ( $FC \geq 2.0$ ) from those observed in normal mucosa and also significantly different from those of MMR-proficient cancers. Intersection of the dark gray circle and the light gray circle on the right defines 18 other genes with expression levels in MMR-proficient cancers that differed significantly ( $FC \geq 2.0$ ) from those of normal mucosa and also from those of MMR-deficient cancers. These 39 genes represent a subset of the MMR-status signature gene set, which we refer to as the MMR-related tumorigenesis signature.

genes *caspace 2*,<sup>32</sup> *BCL10*,<sup>33</sup> *IL1RII*,<sup>34</sup> and *GAS2L1*,<sup>35</sup>; the transforming growth factor  $\beta$  effector *SMAD4*,<sup>36</sup>; the matrix metalloproteinase *HME37*; and *SPP1*, which mediates the tumor suppressor function of p53 by activating host immunosurveillance.<sup>38</sup> The reportedly lower frequency of p53 mutations in MMR-deficient colon cancers<sup>39</sup> is consistent with evidence of enhanced transcription of several p53-induced genes (eg, *p21<sup>Waf1/Cip1</sup>*,<sup>40</sup> *Maspin*,<sup>41</sup> and *DR-NM23*<sup>42</sup>) in our MMR-deficient cancers and cell lines (Supplementary Table 2, see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)). The nonsignificance of this difference in the cancer specimens is probably due to the presence of wild-type p53 in stromal cells, which would attenuate differences related to the higher frequency of epithelial cell p53 mutations in MMR-proficient cancers.

Other genes displaying higher expression in MMR-deficient cells are involved in the antitumoral immune response, including *4-1BBL*,<sup>43</sup> *WSX-1*,<sup>44</sup> *MICB*,<sup>45</sup> *FCGR3A*,<sup>46</sup> and *granzyme A*.<sup>47</sup> In contrast, the granzyme A inhibitor, *SPINK1*,<sup>48</sup> was markedly underexpressed in MMR-deficient cancers, an alteration that should enhance the antitumoral effects of natural killer cells and cytotoxic T lymphocytes.

Overexpression of *4-1BBL* was also documented at the protein levels. This gene is constitutively expressed by activated antigen-presenting cells (eg, dendritic cells, B cells, macrophages) but also by several leukemia and carcinoma cells.<sup>49</sup> Interaction of *4-1BBL* with the tumor necrosis factor receptor 4-1BB plays a crucial role in the response of memory CD8 T cells to tumor cells<sup>43,50</sup> and is an important determinant of effective antitumoral

<i>14-3-3 β</i>	(A)23	3'UTR	Decreased	
<i>ZC3HAV1</i>	(T)23, (A)30	3'UTR	Decreased	

NOTE. In all 154 genes analyzed, mononucleotide repeats in the 3'UTRs were much longer than those in the 5'UTRs and coding regions, which is consistent with a previous observation (Park et al, Cancer Res 2002;62:1284). We therefore limited our search to coding-region and 5'UTR microsatellites consisting of  $\geq 8$  repeat units and 3'UTR microsatellites with  $\geq 12$  repeat units.

MMR(+), MMR proficient; MMR(-), MMR deficient.

<sup>a</sup>To our knowledge, only 2 of these genes have previously been identified as MSI targets: *TGFBR1*<sup>43</sup> and *UVRAG*<sup>50</sup> (the latter based on the analysis of cDNA microarray data). Several known MSI targets (*BAX*, *MSH3*, *RACK7*, *CBF2*, *RECQL1*, and *MRE11*) also displayed MMR(-)-related down-regulation in our study, but they are not included in this table because the decreases were not statistically significant in both the colon cancers and colon cancer cell lines.

<sup>b</sup>Transcript levels in MMR(-) cancers and MMR(-) cell lines versus expression levels in their MMR(+) counterparts. MMR(+) expression levels were not significantly different from those observed in normal mucosal samples except for 4 genes as labeled with a footnote; in these cases, the decreased expression in MMR(-) cancers and cell lines reflects an MMR(+)-related increase over normal mucosal levels.

**Figure 5.** 4-1BBL messenger RNA (mRNA) and protein expression in MMR-deficient and MMR-proficient colon cancer cell lines. (No data are shown for 5 of the cell lines, which could not be reliably analyzed with flow cytometry.) (A) Gray bars represent mRNA levels based on raw signals (y-axis) detected in MMR-deficient (x-axis; left) and MMR-proficient (x-axis; right) cell lines with the Affymetrix U95v2 microarray. (B) Gray bars represent mRNA levels for the 4-1BBL coding region in MMR-deficient (left) and MMR-proficient (right) cell lines determined by quantitative reverse-transcription polymerase chain reaction (RT-PCR); white bars represent corresponding levels for amplification of the control housekeeping gene *GAPDH*. The 4-1BBL coding region was amplified with primers complementary to the exon 2/exon 3 boundary (forward) and to the central region of exon 3 (reverse). The number of cycles (y-axis) at the beginning of the log-phase amplification is inversely correlated with the abundance of the transcript. (C) Gray bars represent cytoplasmic membrane expression of 4-1BBL polypeptide assessed by flow cytometry. Jurkat and Raji cells (white bars) were used as negative and positive controls, respectively, and expression values in colon cancer cell lines were normalized to that of Raji cells. All RT-PCR and flow cytometry assays were performed in duplicate.

and relatively good prognosis that characterize these tumors.

MSI could conceivably be responsible for the decreased transcript levels of genes containing 5'-UTR or coding-

region microsatellites (Table 5). Alterations in the 5'-UTR could diminish transcription efficiency, whereas coding-region MSI would lead to nonsense-mediated decay of the RNA transcript.<sup>52</sup> In contrast, genes whose 3'-UTRs contained long mononucleotide repeats generally displayed increased expression in MMR-deficient settings, and the 3 genes of this type tested for MSI all displayed repeat shortening. The fact that in reverse-transcription polymerase chain reaction the microsatellite-containing tracts of the 3'-UTRs of these genes (but not their coding regions) were amplified much more efficiently in MMR-deficient cells (Supplementary Figure 1, see supplemental material online at [www.gastrojournal.org](http://www.gastrojournal.org)) is difficult to explain, but recent evidence suggests that poly(U)-tract length can affect RNA stability and processing and translation efficiency.<sup>53-56</sup>

#### **Supplemental Information on Experimental Procedures**

##### *Microarray analysis*

Raw gene-expression data generated by MAS software (Affymetrix) were imported for analysis into the GeneSpring software program (Silicon Genetics) and subjected to a double normalization procedure: per chip (normalization to the 50<sup>th</sup> percentile of all values on a given array) and per gene (normalization to the median expression level of the given gene across all samples). Data interpretation was carried out in the log-of-ratio mode with the cross-gene error model turned on. Genes with low expression levels were excluded from analysis by filtering out probes with "absent calls" and/or raw signals < 200 in more than 50% of the samples in each group.

Unsupervised and supervised hierarchical clustering analyses were performed using the Pearson correlation coefficient to measure similarities and a separation ratio of 1 for merging similar branches. A second unsupervised approach known as Principal Component Analysis (PCA) was also used. PCA reduces the dimensionality (number of variables) of a data set while retaining most of its original variability.

It identifies independent dimensions or "components" within a multidimensional gene data set, which account for or explain variance within the set. These components are then ranked (component 1, component 2, etc.) based on the decreasing fraction of data set variance they explain. In addition, within each component, each gene is assigned a PCA value ranging from - 1.0 to 1.0, which indicates its relative impact on that component. Values at the extremes of this range indicate maximal influence, while those closer to zero reflect minimal influence. For our analysis, the GeneSpring program identified the nine dimensions (principal components 1-9) that accounted for the highest percentages of global variability in the data set. We focused our attention on components 1 and 2, i.e., those explaining the largest amounts of variance, and attempted to correlate them with the MMR phenotype of cancers. For the purposes of our analysis, only PCA values between 0.7 and 1.0 (or -0.7 and -1.0) were considered to be significant.

For supervised statistical group comparison analyses, a non-parametric test (Mann-Whitney) was used with a False Discovery Rate of 0.05 and Benjamini-Hochberg Multiple Testing correction; for comparison of normal mucosal tissues and cancers, which yielded larger inter-group differences, Bonferroni correction was used to increase the stringency of the analysis.

#### *Flow Cytometry*

The expression of the 4-1BBL protein was evaluated in colon-cancer cell lines by flow cytometry. After 5 minutes of incubation in 20 mM EDTA in PBS,  $1.2 \times 10^6$  cells from each line were harvested, washed with PBS, and incubated for 30 minutes at 4°C in blocking buffer (1% BSA in PBS). After centrifugation, the cell pellet was

resuspended in FACS buffer (2% FCS and 0.01% sodium azide in PBS) containing 500 µg/ml of the monoclonal antibody against 4-1BBL (anti-human CD137, Immatics) and incubated for 2 hours on ice. A control incubation with isotype IgG1 was performed for each sample. Cells were then washed twice in FACS buffer and incubated in this buffer with the secondary anti-mouse goat FITC-conjugated antibody for 45 minutes on ice. After two additional washings in FACS buffer, cells were fixed in 1% formaldehyde in PBS and analyzed in a Coulter Epics Altra flow cytometer (Beckman-Coulter). Data were analyzed using Microsoft WinMDI Expo 32 software (version 1.28).

**Supplemental Table S1. Genes displaying significantly different expression levels in proximal colon cancers compared with normal mucosal specimens (regardless of MMR status).**

\* Statistical significance was assessed with the Mann-Whitney test with a False Discovery Rate of 0.05 and Benjamini-Hochberg Multiple Testing correction. Minimal fold difference: 2.0. Genes whose differential expression was characterized by fold differences < 2.0 are not shown, even if statistically significant.

Underlined: Genes displaying similar patterns of differential expression [MMR(+) vs. MMR(-)] in both colon cancers and colon-cancer cell lines (No fold change restriction was applied to colon cancers)

Supplemental Figure S1, di Pietro et. al.

**Supplemental Figure S1 - *NUTF2* mRNA expression in MMR(-) and MMR(+) colon-cancer cell lines.** **A.** Gray bars represent raw signals for *NUTF2* expression detected in MMR(-) (x-axis - left) and MMR(+) (x-axis - right) cell lines with the Affymetrix U95v2 microarray. **B.** Quantitative RT-PCR amplification of the coding region (black bars) and 3'UTR (gray bars) of *NUTF2* mRNA and the control housekeeping gene *GAPDH* (white bars) in MMR(-) (left) and MMR(+) (right) cell lines. The height of the bars, which corresponds to the number of cycles (y-axis) at the beginning of the log-phase amplification, is inversely correlated with the abundance of transcript. No bars are shown for the amplification reaction of the 3'UTR in MMR(+) cell lines because no PCR product was obtained by RT-PCR. The RT-PCR findings were consistent with the results of the microarray analysis because, for this gene (and most of the others represented on the array), the Affymetrix chip includes probes complementary to both the 3'UTR and the 3' end of the coding region. **C.** The poly(T) repeat in the 3'UTR of *NUTF2* cDNA is shown in red, the coding sequence in blue. Primers for the amplification reactions shown in Panel B are indicated by bold-faced type.

## Abstract

**Background & Aims.** The incidence of adenocarcinomas in the small intestine, particularly in the ileum, is much lower than in the colon, which arises in the third most frequent cancer type both in men and women.

Even though the anatomical and physiological ileum/colon transition has been well described, the molecular explanations for the different cancer frequency in these two similar tissues have not been completely explained.

Our aim was to analyze the transcriptomes of colon and ileum normal mucosas to find out the pathways, and the key genes of those pathways, that could explain this phenomenon.

**Methods.** A prospective study was conducted on 12 paired colon and ileum normal mucosa samples collected endoscopically.

The transcriptome of the entire human genome was investigated using a well-standardized gene-expression platform.

**Results.** Unsupervised analyses of microarray data clearly distinguished ileum from colon normal mucosa samples. We found many conspicuous expression changes of genes involved in cell differentiation/proliferation, transcription regulators, Wnt-signaling pathway and apoptosis in these two tissues.

We focused our attention on two pro-apoptotic genes members of the cell death-inducing DFFA-like effectors family, *CIDEB* and *CIDEC*, which were very down-regulated in colon compared to the counterpart ileum samples. We also found their mRNA levels further down-regulated in colon adenomas and adenocarcinomas. Work at the protein level is currently in progress..

**Conclusions.** We have reported for the first time a comparative analysis of the gene expression profile of human colon and ileum normal mucosa. Among the up-regulated genes in ileum, we pointed out *CIDEB* and *CIDEC*, known to be involved in apoptosis, as two genes that may play an important role in prevention of colorectal tumorigenesis.

## Introduction

The small intestine (duodenum, jejunum and ileum) constitutes about the 75% of the total length of the gastrointestinal tract (GI) but only 1-3% of the GI malignances appear in this portion (>50 times less frequent than malignances in the colon)<sup>1</sup>. Only around 40% of these malignances are adenocarcinomas (i.e., derived from epithelial cells) and 80% of them arise in the duodenum and jejunum (proximal small intestine) while they are rare in the longer and distal part (closer to the colon), the ileum<sup>1</sup>. On the opposite side, colorectal adenocarcinoma is the third most frequent cancer type both in men and women and its frequency is about 25 times higher than in the small intestine<sup>2</sup>.

Although the anatomical and physiological transition between ileum and colon is well characterized, the molecular features underlining the different adenocarcinoma incidence in ileum and colon are not known although many studies about the effect of luminal factors<sup>3-5</sup> (for example the gut microflora, carcinogens, etc) and intrinsic differences<sup>6-8</sup> (for instance cell turnover rates, the redox status, etc...) have been complete to date. It is generally accepted that the amount and distribution of mucosal and luminal factors is different in these two GI tracts and that this might be important in modulating the predisposition to adenocarcinoma.

On the other hand, our knowledge about the molecular basis of colon adenocarcinomas has been substantially increased in the last 20 years. The sequence of events required to transform normal human colonic epithelium into sporadic adenomas and carcinomas has been documented<sup>9-13</sup>.

Our aim in this study was to show for the first time a transcriptional analysis between the colon and the ileum normal mucosas. We think this may be the first step to find out the molecular features responsible for the different adenocarcinoma incidence in these two physic- and physiological similar tissues.

The wider vision of the molecular changes occurring in these two healthy tissues upcoming from this analysis can help us, and other scientists, to focus our effort in certain molecules or pathways which could enclose the explanations to this scenario.

Among all the genes found differently expressed in colon compared to ileum normal mucosa, those related to apoptosis, cell proliferation and differentiation, regulators of transcription, immune response and cell defense, may possibly be the most interesting ones to work with.

We have focused our attention on apoptosis and, particularly, on *CIDEB* and *CIDEA* genes.

Apoptosis is the regulated, or programmed, cell death of those cells that are not necessary anymore or that are potentially dangerous for the organism<sup>14</sup>. A family of cysteine proteases, called caspases, have been shown to play a key role in this process<sup>15, 16</sup>. Another important group of pro- and anti-apoptotic regulators are the Bcl-2 family, in which the protein-protein interactions are very important to understand their mechanism of action<sup>17-19</sup>. Although many high-quality articles have been published up to date, there's still a lot of work to do on the understanding of the regulation of this process and on the development of new therapies for human diseases<sup>20</sup>.

*CIDEB* and *CIDEC*, also called cell death-inducing DFFA-like effector b and c, respectively, are members of the CIDE family of genes (*CIDEA*, *CIDEB* and *CIDEC*). These genes have homology to the N-terminal region of *DFFA* (*DFF40/CAD*) and *DFFB* (*DFF45/CAD*) (DNA fragmentation factor, 45kDa, alpha polypeptide and 40kDa, beta polypeptide, respectively)<sup>21</sup>. DNA fragmentation factor (DFF) is a heterodimeric protein of 40-kD (DFFB) and 45-kD (DFFA) subunits. DFFA is the substrate for caspase-3 and triggers DNA fragmentation during apoptosis. DFF becomes activated when DFFA is cleaved by caspase-3 and dissociate from DFFB, its inhibitor. DFFA has been found to trigger both DNA fragmentation and chromatin condensation during apoptosis<sup>22, 23</sup>.

It has also been shown that as well as the caspase-3 triggered activation of DFFA, the nuclease activity of this gene seems to be regulated by the interaction between DFFB and *CIDEB*. *CIDEB*, thanks to the strong homology to the regulatory CIDE-N domain of DFFA and DFFB and to the fact that CIDE-N/CIDE-N interaction between DFFB and *CIDEB* is stronger than between DFFA and *CIDEB*, sequesters DFFB from the heterodimer complex that forms with DFFA, triggering apoptosis<sup>24</sup>.

Since has been described that *CIDEC* most probably have an important role in prevention of tumorigenesis<sup>25</sup> and based on the strongly cell-specific hyper- or hypo-methylation dependent regulation of *CIDEB*'s promoter<sup>26</sup>, we assume that *CIDEB* and *CIDEC* may play an important role in colorectal tumorigenesis prevention.

## Material and Methods

### ***Colon and Ileum normal mucosa samples***

Samples from right-side colon and from ileum were prospectively collected by F.B. and A.S. at the gastroenterology unit of the Triemli Hospital (Zurich, Switzerland) with full institutional review-board approval. The fact that the sampling was done only by two operators, using exactly the same procedure, minimized artifacts due to sampling differences. After resection, tissues were immediately immersed in RNAlater (Ambion, Huntington, UK), to preserve RNA from degradation, for subsequent microarray analysis.

Total RNA was extracted (RNeasy Mini kit, Qiagen, Hilden, Germany) from homogenized 5- to 15-mg tissue samples and its integrity was verified by capillary gel electrophoresis (Bio Analyzer, Agilent Technologies, Santa Clara, CA). Total RNA was converted to cDNA using a cDNA synthesis kit (Invitrogen, Carlsbad, CA). Double-stranded cDNA was then converted to biotin-labeled cRNA by a T7 RNA polymerase-catalyzed reaction (MEGA Script in vitro transcription kit, Ambion, Austin, TX) with biotin-containing nucleotides from LOXO (Dossenheim, Germany). Labeled cRNA were then purified (RNeasy kit, Qiagen, Hilden, Germany) and fragmented. 15 µg cRNA were hybridized with Affymetrix U133A arrays (High Wycombe, UK), which contains 22823 *in situ* synthesized oligonucleotides representing more than 14,500 genes.

### **Microarray Analysis**

Raw gene-expression data generated by GCOS software (Affymetrix) were imported into the GeneSpring software program (Agilent) and normalized per chip (i.e., to the median of all values on a given array) and per gene (i.e., to the median expression level of the given gene across all samples). Analysis was performed using the log expression values with GeneSpring's cross-gene error model turned on. Only probes listed as "present or marginal calls" and/or with expression values  $\geq 100$  in at least 50% of the samples (6 out of 12) in either tissue groups (that means: only in colon or only in ileum, or in both groups) were included in further analyses.

Expression data were subjected to four different unsupervised analyses: 1) Hierarchical clustering using the Pearson correlation coefficient as a similarity measure and the average linkage algorithm for branch merging; 2) Principal Component Analysis (PCA) which reduces the dimensionality (number of variables) of a data set while retaining most of its variance. PCA identifies independent "components" within a multidimensional gene data set, which account for or explain variance within the set. These components are then in decreasing order based on the fraction of data set variance they explain. In addition, within each component, each gene is assigned a PCA value ranging from - 1.0 to 1.0, which indicates its relative impact on that component. Values at the extremes of this range indicate maximal influence, while those closer to zero reflect minimal influence; 3) Correlation Analysis which involved computation of Pearson correlation coefficients for all possible sample pairs and visualization of correlation values as tile plots; 4) Correspondence Analysis (CA), another dimension-reducing method<sup>27</sup>, that was used to identify samples associated with particular gene expression levels. Typically, CA treats a matrix of  $n$  gene expression levels from  $p$  samples as a two-way contingency table (genes by samples or vice versa) with  $n$  and  $p$  specifications for the "factors" gene and sample, respectively. Hereby, each intensity value is viewed as an abundance value of a particular transcript in a particular sample. Like PCA, CA identifies independent "factorial components" within a multidimensional gene data set, which account for variance within the set, but in this case the components are identified and ranked according to the correlation between gene and sample scores. CA and its plot, was computed using R and the contributed packages "ade4" as well as "made4", all available from Bioconductor (<http://www.bioconductor.org>.)

We then selected the genes differentially expressed in colon normal mucosa compared to the ileum normal mucosa using the Mann-Whitney test, a False Discovery Rate of 0.01 and the Benjamini-Hochberg Multiple Testing correction. We then analyzed these genes to identify any biological processes from the Gene Ontology database<sup>28</sup> that were over-represented. ErmineJ software<sup>29</sup> was used for this latter analysis.

### **Real-Time RT-PCR**

One-step real-time retro-transcription poly chain reaction (real time RT-PCR) was performed with the Roche LightCycler System using the Light Cycle-RNA Master Sybr Green I Kit (Roche, Basel, Switzerland) according to the manufacturer's instructions, 0.3  $\mu$ M of each oligonucleotide primer (Microsynth, Balgach, Switzerland) and 150 ng of total RNA in 20  $\mu$ l of reaction volume. Primer sequences

and RT-PCR reaction conditions are available on request. The Ct is the cycle corresponding to the beginning of the log-phase amplification and one cycle difference in Ct corresponds, theoretically, to a 2-fold change in RNA concentration. Fold changes were obtained by normalizing to GAPDH used as internal control. All of the experiments were performed in duplicate, and the specificity of each amplification product was verified by agarose gel electrophoresis. Primers are available on request.

### ***Immunohistochemistry***

Sections (4  $\mu$ m) of formalin-fixed, paraffin-embedded tissues were mounted on silanized slides, deparaffinized and rehydrated. Antigen was retrieved by heating the sections in a pressure cooker (120°C for 2 min) in 10 mM citrate-buffered solution (pH 6.0). Peroxidase-blocking reagent and goat serum (DakoCytomation, Glostrup, Denmark) were used sequentially to eliminate non-specific staining due to endogenous peroxidase activity and unspecific antibody binding, respectively. The sections were incubated at 4°C for 24 hours with a 1:1000 dilution of the affinity-purified CIDEB antibody. After washing, anti-rabbit secondary antibodies conjugated to peroxidase-labeled polymer (DakoCytomation EnVision+ kit) were applied for 30 min at RT. The peroxidase activity was then developed by incubation with 3,3'-diaminobenzidine chromogen solution. Negative control experiments were carried out with CIDEB antibody that had been pre-absorbed with the immunogenic peptide; alternatively, primary or secondary antibodies were omitted altogether.

## **Results**

Twelve matched couples of right-side colonic and ileal normal mucosa samples were collected after surgical operations from 12 different patients.

Microarray data analysis for the 12 colonic-ileal normal mucosa paired samples revealed that 16245 of the 22283 probes present in the HG-U133A arrays were expressed in either one or both tissue groups. Four different unsupervised analyses of the transcriptional levels of the expressed genes effectively segregate the colonic normal mucosa group from the ileal one (**Figure1**).

One thousand six hundred fifty-two of the expressed probes showed significant expression changes in colon compared to ileum normal mucosa after supervised statistical analysis (**Figure 2A**). To identify the main different biological processes in each tissue group, we performed a Gene Ontology analysis with all the differentially expressed genes. The colonic normal mucosa samples had an up-regulation of genes mainly involved in both positive regulation of cell motility and cell migration. On the other hand, genes up-regulated in the ileum normal mucosa group were related to different aspects of metabolism, protein kinase C activation and regulation of apoptosis, among others (**Table 1**).

In order to try to uncover the most important transcriptional changes between these two tissues, we have selected those genes with a fold change  $\geq 4$ , the ones that more significantly distinguished the

two groups of samples (**Figure 2B** and **Table 2**). This list is meant to be a starting point for future confirmation studies. We found 213 genes significantly up-regulated (n=52) or down-regulated (n=161) in colon normal mucosa compared to their counterpart ileum samples.

Because it is thought that specific pathways maintain the cellular homeostasis in the normal tissue and those controlling the normal proliferation/differentiation rates in the colon could be differently regulated in the ileum, we focused on the changes in the expression levels of genes involved in these pathways as well as of numerous transcription regulators (**Table 3**). We included those genes with fold changes between 4 and 2 because small changes of such molecules could still enclose very important information.

We have also focused our attention on the Wnt signaling pathway; it's the physiological regulator of epithelial homeostasis and has been well described in the literature that the transformation process to adenoma, and lately to carcinoma, begins in the epithelial crypts as a result from qualitative, quantitative and spatial subversion of this pathway<sup>11, 12, 30-32</sup>. Although the list of Wnt target genes is far to be completed, many studies have been performed<sup>33, 34</sup>. Thus, we have analyzed the expression levels of the members and targets of this pathway in ileum and colon (**Table 3**).

Given the very high rates of cell renewal in ileum and colon and the importance of apoptosis for this process, we focus on the analysis of the expression level of apoptosis-related genes in these two tissues to see whether we could find relevant differences that could give a hint on the reasons why the cancer incidence is much higher in colon than in ileum (**Table 4**). Amongst those genes more expressed in ileum, we focused our attention in *CIDEB* and *CIDEC*, the two members of the cell death-inducing DFFA-like effectors expressed in these two tissues. The third member of this family, *CIDEA*, was neither expressed in the ileum nor in the colon normal mucosa samples (data not shown). The mRNA over-expression of *CIDEB* and *CIDEC* in all 12 ileum normal mucosa was conspicuous compared to the 12 counterpart colon normal mucosa samples (7.6 and 8.3 times, respectively). Interestingly, the expression of these two genes was also found down-regulated in benign and malignant colorectal tumors previously studied by our group<sup>35, 36</sup> (**Figure 3A**). The microarray results for *CIDEB* were confirmed by real-time RT-PCR analysis (**Figure 3B-D**). Given that for *CIDEB* two different transcripts were described<sup>26</sup>, we also showed that the difference in expression level between ileum and colon was in the short one whereas the long one remained unchanged in both tissues. At this point, we also checked the mRNA levels in our microarray data for SP1, SP3 and HNF4-alfa because they have been shown to regulate the two different *CIDEB* transcripts (SP1 and SP3 both and HNF4-alfa only the short one) together with hypermethylation of the up-stream promoter<sup>26</sup>. The mRNA expression levels of these genes were not significantly changed among the different tissue groups, ileum, colon, adenomas and carcinomas, we had (data not shown).

We are currently analyzing the protein level of *CIDEB* and *CIDEC* in mouse and human tissues with preserved architecture to identify their cellular localization (work in progress, data not shown).

## Discussion

Why cancer frequency in colon is tremendously higher than that in ileum even though these two gastrointestinal segments are physically and morphologically very similar? To date, little is known about the possible molecular mechanisms behind this phenomenon. We attempted to answer this question by performing a comprehensive comparison of colon and ileum normal mucosa transcriptomes using the latest cDNA microarray technology.

The transcriptome of the colon normal mucosa, compared with that of ileum normal mucosa, shows the molecular differences existing between these two tissues, although, as expected because of the similar nature of both organs, they are less numerous than between colorectal tumors and colon<sup>35, 36</sup>.

From the 1652 probes found significantly changed between these two tissues, we have drawn up a list of 213 genes up- (n=52) or down-regulated (n=161) in colon compared to ileum with a fold change  $\geq 4$ . We think that this list can be used as a starting point for future verification studies.

We have shown a complete picture of the expression changes on genes related to cell proliferation/differentiation, transcription regulators, Wnt signaling and apoptosis that may elucidate the reasons why the adenocarcinoma incidence in ileum and colon is so different.

We also focused on two pro-apoptotic genes highly up-regulated in ileum compared to colon, *CIDEB* and *CIDEA*. The expression of these two genes, members of the cell death-inducing DFFA-like effectors family, is even more decreased in colon adenomas and adenocarcinomas.

It has been shown that *CIDEB* has two different transcripts. We have revealed that is the short one which is down-regulated in colon, and even more in adenomas and adenocarcinomas of the colon, compared to ileum. These results suggest that *CIDEB* and *CIDEA* may play an important role in colorectal tumorigenesis prevention.

For *CIDEA* has already been shown that may play an important role in prevention of tumorigenesis in kidney, liver and melanoma cell lines<sup>25</sup> but neither *CIDEB* nor *CIDEA* decreased expression levels were yet related to increased incidence of colorectal adenocarcinomas.

Work at the protein level is currently on progress and we expect it will bring valuable information about their cellular localization and putative roles against carcinogenesis.

## Figure Legends

### **Figure 1. Unsupervised Analyses of microarray data**

**(A) Hierarchical clustering analysis:** The 24 tissue samples represented on the x-axis include 12 colon (red branches) and 12 ileum (green branches) normal mucosal samples. Each of the 16245 expressed probes plotted on the y-axis is color-coded to indicate the expression level of the gene relative to its median level of expression across the entire set of tissue samples (blue: low; red: high). **(B) Principal**

*component analysis (PCA)*. Profile plot of the normalized first principal component (PCA-1) across the 24 specimens (green dots: colon normal mucosa; red dots: ileum normal mucosa). The two tissue groups are significantly different in terms of the first principal component ( $p < 0.0001$ ), which accounted for 30% of the total variance. **(C) Correlation Analysis**. Tile-plot visualization of the pair-wise correlations of the samples. The correlation matrix has 24 rows and columns corresponding to the 24 samples. The gray scale column at the right side of the tile-plot refers to the correlation values (white: high correlation; black: low correlation). The matrix shows that colon or ileum normal mucosa samples are highly correlated among each other (lower left and upper right part). Colon and ileum normal mucosa samples are poorly correlated (upper left and lower right part), however, the samples from the same patient generally show a higher correlation than colon and ileum samples from different patients (bright pixels on the secondary diagonals in the upper left and lower right part). This finding probably reflects the strong influence of several factors, including the individual genetic background and life-style. **(D) Correspondence Analysis (CA)** of mRNA log(intensity) values of expressed genes from the 12 tissue pairs (colon normal mucosa, red dots; ileum normal mucosa, green dots). The areas delimited by the ellipses represent 95% of the estimated bi-normal distribution of the sample scores on the first and second CA axes. The map of the sample scores on the first two axes shows that CA efficiently discriminates between colon and ileum normal mucosa samples.

**Figure 2. Supervised Hierarchical Analysis of microarray data**

**(A) All statistically significant probes**: As in Figure 1, 12 colon (red branches) and ileum (green branches) normal mucosa samples are represented in the x-axis. In this case, on the y-axis, we have plotted all the probes that passed the statistical analysis (Mann-Whitney test, False Discovery Rate of 0.01 and the Benjamini-Hochberg Multiple Testing correction). Each of the 1652 statistically significant probes plotted on the y-axis is color-coded to indicate the expression level of the gene relative to its median level of expression across the entire set of tissue samples (blue: low; red: high). **(B) Statistically significant probes with a fold change  $\geq 4$** : As in Figure 1, 12 colon (red branches) and ileum (green branches) normal mucosa samples are represented in the x-axis. On the y-axis, only the 267 statistically significant probes with a fold change  $\geq 4$  (representing 213 different genes) are plotted. The color-code is the same as in (A).

**Figure 3. CIDEB and CIDEA messenger RNA expression in tumors and normal mucosa of the colon and ileum.**

**(A) CIDEB and CIDEA mRNA levels** detected in samples of ileum and colon normal mucosa and colorectal adenomas and carcinomas (normalized data of the raw signal values (y-axis)). Whereas CIDEB and CIDEA mRNA levels in ileal normal mucosa were 7.6 and 8.3 times higher than those found in the colonic normal mucosa, levels in colorectal adenomas and carcinomas were at least 2 times lower. All these differences were highly significant ( $*p < 0.001$ ;  $**p < 2.5e-7$ ;  $***p < 1.2e-8$ ). **(B) Real-time RT-PCR amplification** of the two different transcripts of CIDEB and the control housekeeping gene GAPDH in one ileum and one colon normal mucosa and in one colorectal adenoma and one carcinoma

representative samples. A total of 5 samples for each tissue were examined in triplicate. Ct (threshold cycle): number of cycles (x-axis) at the beginning of the log phase of amplification. After 37 cycles of PCR, the long transcript of *CIDEB* (Lt) was equally amplified in all samples whereas the short transcript (St) was increasingly amplified in ileum, colon, adenomas and carcinoma samples. **(C)** Melting curve picks for Lt and St *CIDEB* and *GAPDH*. The specificity of the products obtained is very clear. **(D)** The *CIDEB* amplification products were subjected to agarose-gel electrophoresis to verify the specificity of the amplification. M: 100-bp ladder marker; NC: Negative Control; IL: ileum normal mucosa; CO: colon normal mucosa; Ad: adenoma; CRC: carcinoma.

feeding behavior	13	4	6.78E-03
glutathione metabolism	8	3	8.13E-03
alkene metabolism	8	3	8.00E-03

\* Number of genes annotated in the corresponding Gene Ontology category

^ Number of genes from each category that were found significantly up- or down-regulated in colon normal mucosa

# p-value corrected for multiple testing as reported in: Lee HK et al. "ErmineJ: Tool for functional analysis of gene expression data sets" BMC Bioinformatics 2005; 6:269

**Table 2.** Gene with markedly altered expression between ileum and colon normal mucosa (fold-differences of  $\geq 4.0$ ) (Statistical significance was assessed with the Mann-Whitney test using a False Discovery Rate of 1% as a threshold)

### Abstract

The human mismatch repair (MMR) proteins hMLH1 and hPMS2 function in MMR as a heterodimer. Cells lacking either protein have a strong mutator phenotype and display microsatellite instability, yet mutations in the *hMLH1* gene account for ~50% of hereditary nonpolyposis colon cancer families, whereas *hPMS2* mutations are substantially less frequent and less penetrant. Similarly, in the mouse model, *Mlh1*<sup>-/-</sup> animals are highly cancer prone and present with gastrointestinal tumors at an early age, whereas *Pms2*<sup>-/-</sup> mice succumb to cancer much later in life and do not present with gastrointestinal tumors. This evidence suggested that MLH1 might functionally interact with another MutL homologue, which compensates, at least in part, for a deficiency in PMS2. Sterility of *Mlh1*<sup>-/-</sup>, *Pms2*<sup>-/-</sup>, and *Mlh3*<sup>-/-</sup> mice implicated the Mlh1/Pms2 and Mlh1/Mlh3 heterodimers in meiotic recombination. We now show that the hMLH1/hMLH3 heterodimer, hMutLγ, can also assist in the repair of base-base mismatches and single extrahelical nucleotides *in vitro*. Analysis of hMLH3 expression in colon cancer cell lines indicated that the protein levels vary substantially and independently of hMLH1. If hMLH3 participates in MMR *in vivo*, its partial redundancy with hPMS2, coupled with the fluctuating expression levels of hMLH3, may help explain the low penetrance of *hPMS2* mutations in hereditary nonpolyposis colon cancer families. (Cancer Res 2005; 65(23): 10759-66)

### Introduction

Mismatch repair (MMR) proteins are a highly conserved group of polypeptides that play key roles in the correction of mispairs arising during DNA replication. They also prevent recombination between nonidentical sequences and participate in the signaling of certain types of DNA damage. The importance of MMR proteins in the maintenance of genomic integrity is underscored by the finding that germ line mutations in *MMR* genes predispose to hereditary nonpolyposis colon cancer, a common familial cancer predisposition syndrome (reviewed in refs. 1, 2). The principal MMR players in human cells are homologues of the bacterial MutS and MutL proteins. hMutSα, a heterodimer of the MutS homologues hMSH2 and hMSH6, binds base-base mismatches and small insertion/deletion loops, whereas hMutSβ (a heterodimer of hMSH2 and hMSH3) binds only insertion/deletion loops. This *in vitro* evidence

could be corroborated by analysis of the phenotypes of MMR-deficient cells: Those lacking hMSH2 are fully MMR deficient and display a mutator phenotype and microsatellite instability that is consistent with the loss of repair of both base-base mismatches and insertion/deletion loops. Cells lacking hMSH6 retain a strong mutator phenotype but their microsatellite instability is limited to mononucleotide repeats due to the functional redundancy with hMutSβ in insertion/deletion loop repair. This situation is mirrored in hereditary nonpolyposis colon cancer families, where the penetrance of *hMSH2* mutations is substantially higher than that of alterations in the *hMSH6* locus (reviewed in ref. 2).

Whereas it is generally accepted that hMutSα and hMutSβ are the mismatch recognition factors that initiate MMR (reviewed in ref. 3), the function of the MutL homologues remains speculative. The human genome contains numerous genes that have significant sequence homology to *mutL* and to yeast MutL homologue and postmeiotic segregation genes; however, to date, only hMutLα, a heterodimer of hMLH1 and hPMS2, could be shown to be involved in MMR. Correspondingly, hMLH1- or hPMS2-deficient cells have a strong mutator phenotype and high microsatellite instability (reviewed in ref. 1). In *in vitro* studies, hMutLα could be shown to associate with hMutSα on a mismatch-containing substrate (4) and was suggested to act as a "molecular matchmaker" between these protein complexes and the downstream effectors of repair (reviewed in ref. 3). hMutLβ, a heterodimer of hMLH1 and hPMS1, has been biochemically characterized but could not be shown to participate in MMR *in vitro* (5). This finding was substantiated by *in vivo* evidence: Mice carrying a disruption in the *Pms1* gene display neither microsatellite instability nor cancer predisposition (6). hMLH3 was identified through its interaction with hMLH1 on Far Western blots (7); however, this heterodimer, hMutLγ, has not been biochemically characterized and its role in mammalian MMR has not been established. *MLH3* was first identified in *Saccharomyces cerevisiae* and its gene product, scMlh3p, was shown to bind scMlh1p (8, 9) and to be involved in meiotic recombination (reviewed in refs. 10, 11). As *mlh3* mutants display a mutator phenotype similar to that of *msh3*-deficient strains (8, 12), it was suggested that the two polypeptides are involved in the repair of a subset of insertion/deletion loops. hMLH3 seems to be involved in meiotic recombination (13, 14) and the same is true for the murine Mlh3 (14). As both Mlh1- and Mlh3-deficient mice are sterile (reviewed in refs. 10, 11), it was suggested that the two polypeptides function together. However, unlike *Mlh1*<sup>-/-</sup> animals (6), *Mlh3*<sup>-/-</sup> mice did not succumb to cancer in the first 9 months of life (15). The roles of the various MMR factors and the phenotypes of mice with defects in *MMR* genes are listed in Table 1.

The involvement of MutL homologue malfunctions in human cancer is not as clear cut as in the case of the MutS homologues. Mutations in *hMLH1* predominate in hereditary nonpolyposis

Table 1. Overview of mammalian MutS and MutL homologues and their roles in MMR

Heterodimer	Components	MMR role	Phenotype of knockout mice
hMutS $\alpha$	hMSH2 hMSH6	Repair of base-base mismatches and small loops	Lymphomas, gastrointestinal, skin, and other tumors
hMutS $\beta$	hMSH2 hMSH3	Repair of loops	Lymphomas, gastrointestinal, and other tumors
hMutL $\alpha$	hMLH1 hPMS2	Repair of all MMR substrates	Lymphomas, gastrointestinal, skin and other tumors; sterility
hMutL $\beta$	hMLH1 hPMS1	?	Lymphomas, sarcomas; male sterility
hMutL $\gamma$	hMLH1 hMLH3	?	Lymphomas, gastrointestinal, skin, and other tumors No phenotype Sterility

colon cancer, accounting for nearly 50% of all known germ line *MMR* gene mutations (2). Surprisingly, no germ line mutations have been found in *hPMS1* or *hPMS2*, which was unexpected, given the key role of the latter protein in MMR. Recent immunohistochemical analysis of 1,048 unselected colon tumors revealed the lack of hPMS2 in ~1.5%, a proportion similar to that of MSH2-deficient cancers (16). Genetic analysis identified germ line mutations in *hPMS2* in a number of these patients and it is likely that the remainder will also be linked to genetic alterations once the problems associated with sequencing of the *hPMS2* locus are overcome (there are ~20 *hPMS2* pseudogenes on chromosome 7, which interfere with DNA sequencing). However, these patients do not belong to typical hereditary nonpolyposis colon cancer families and the penetrance of these mutations seems to be very low. One possible explanation for this finding is that the defect in hPMS2 is partially compensated for by another MutL homologue, such as hMLH3. Germ line *hMLH3* missense and frameshift mutations have been described in familial colorectal cancer cases but the implication of these alterations in carcinogenesis is ambiguous. In some cases, the mutation in *hMLH3* was identified in families carrying a second *MMR* gene mutation, whereas no mutations in the other *MMR* genes could be identified in other cases (17–19). A similar discrepancy applies also to the microsatellite instability status of the tumors (17, 20). The role of hMLH3 in MMR and of *hMLH3* mutations in cancer thus remains open to question. In an attempt to provide answers to these questions, we examined the role of hMLH3 in MMR *in vitro*.

## Materials and Methods

### cDNA Vectors

**pFastBac1-His<sub>6</sub>-hMLH3.** The cDNA of *hMLH3* (Swiss-Prot entry Q9UHC1) was used as template for a PCR reaction where (His)<sub>6</sub> tag was added at the NH<sub>2</sub> terminus of *hMLH3* using the primers hMLH3<sub>361</sub> (5'-CGCGGATCCACCATGTCGTACTACCATCACCATCACCATCAG-ATTACGATATCCCAACGACCGAAACCTGTATTTTCAGGGCATCAAGT-CTTGTCAGTTGAAG-3') and hMLH3<sub>re1</sub> (5'-ATTTGCCTACTGGTGGGACC-3'). The fragment was then cleaved with *Bam*HI and *Pst*MI and cloned between the corresponding sites in pFastBac1 (Invitrogen, San Diego, CA).

**pTXB1-hMLH3 (amino acids 961-1,453).** The COOH-terminal part of *hMLH3* cDNA coding for amino acids 961 to 1,453 was amplified by PCR from pFastBac1-His<sub>6</sub>-hMLH3 using the primers hMLH3-Ct (5'-GGGAATTCATATGGGAGAACTGTGTGATATCAGAACTC-3') and rMLH3-Ct (5'-AAGGCCGCTCTTCGACACATTGGTGGCTCAGAGGAGGCATG-3'). The PCR product was subcloned between the *Nde*I/*Sap*I sites of pTXB1 (New England Biolabs, Beverly, MA).

### Expression of hMutL $\gamma$

The Bac-to-Bac baculovirus expression system (Life Technologies, Gaithersburg, MD) was used according to the instructions of the manufacturer. *Spodoptera frugiperda* Sf9 cells ( $2 \times 10^6$ ; Life Technologies) were infected with either a single recombinant baculovirus or with a combination of two viruses at a multiplicity of infection of 10. Cells were harvested 72 hours after infection and total extracts were prepared as described (21). Partial purification of hMutL $\gamma$  from Sf9 extracts was done using Ni-NTA agarose (Qiagen, Hilden, Germany), and the QIAexpressionist system was used according to the instructions of the manufacturer using 5 mL of 50% Ni-NTA slurry per 100 mg of protein extract.

hMutL $\gamma$  was expressed also in bacteria using a bicistronic vector *pET11b-His<sub>6</sub>-hMLH3/MLH1* (cloning information on request) in the BL21 strain of *Escherichia coli*. After induction of expression at 37°C for 4 hours with 0.4 mmol/L isopropyl- $\beta$ -D-thiogalactopyranoside, the heterodimer was expressed but was insoluble. Nevertheless, the protein could be used to quantify the relative abundance of hMLH3 in HeLa cells.

### hMLH3 Antibody Production and Purification

The COOH-terminal polypeptide of hMLH3 (amino acids 961-1,453) was expressed using the Impact-CN-System (New England Biolabs) in BL21 *E. coli* transformed with *pTXB1-hMLH3* (amino acids 961-1,453). The peptide was purified using fast protein liquid chromatography on a MiniQ 4.6/50 PE column (Amersham Pharmacia, Uppsala, Sweden) and used to immunize rabbits at Eurogentec (Seraing, Belgium). The rabbit polyclonal antibody was then affinity-purified using the COOH-terminal polypeptide immobilized on a nitrocellulose membrane. In brief, 100  $\mu$ g of the purified polypeptide were blotted onto a nitrocellulose membrane by standard electrophoretic transfer, visualized by Ponceau S staining, and the corresponding band was cut out. The membrane was blocked with 5% nonfat dry milk in TBST [20 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, and 0.1% Tween 20] for 60 minutes, incubated with 700  $\mu$ L of the polyclonal antibody for 4 hours at 4°C, and washed thrice with TBST for 15 minutes. The membrane was then cut into small pieces ( $1 \times 0.5$  cm) and the antibody was eluted from the membrane by incubation for 20 minutes at room temperature in 0.1 mol/L glycine (pH 2.5). The supernatant was collected and the pH was neutralized by an equal volume of 1 mol/L Tris-HCl (pH 8.0). The purified antibody was stored at -20°C in 50% glycerol.

It was used to perform all the experiments described in this study except for the immunoprecipitation of hMLH3 from human cell extracts.

### Human Cell Lines and Preparation of Cell Extracts

All the colon cancer cell lines, HEK293, and HeLa cell lines used in this study were obtained from the cell line repository of Cancer Network Zurich. The hPMS2-deficient cell lines HeLa clone 12 (22) and Hec-1A (23) were kindly provided by Dr. Margherita Bignami (ISS, Rome, Italy). The cell line HEK293T was derived from HEK293 by immortalization with adenovirus 5 DNA and transfection with SV40 large T antigen (24). The *hMLH1* gene in this cell line is epigenetically silenced by promoter hypermethylation (25). The 293T L $\alpha$  cell line was developed in our laboratory (26). In these cells, the *hMLH1* cDNA was stably integrated under the control of the tetracycline response promoter

using the Tet-Off system (Clontech, Palo Alto, CA). In the absence of doxycycline, these cells express hMLH1 and are MMR proficient. All the cell lines were cultured at 37°C in a 5% CO<sub>2</sub>-humidified atmosphere and maintained in the appropriate media. Whole cell extracts from these cell lines were prepared as described (26) without modifications. The origin and MMR status of the cell lines used in this study is listed in Table 2.

#### Western Blot Analysis

Western blots were done as previously described (26) using the following primary antibodies: our rabbit polyclonal anti-hMLH3 (1:400), anti-hMLH1 and anti-hPMS2 from BD PharMingen (San Diego, CA) (1:4,000 and 1:1,000, respectively), and anti- $\beta$ -tubulin (1:2,000; Santa Cruz Biotechnology, Santa Cruz, CA).

#### Coimmunoprecipitation Analysis of hMLH1 and hMLH3

HeLa whole cell extract (1 mg) was incubated in a total volume of 500  $\mu$ L in NP40 Lysis Buffer [50 mmol/L Tris-HCl (pH 8.0), 125 mmol/L NaCl, 1% NP40, 2 mmol/L EDTA, 1 mmol/L phenylmethylsulfonyl fluoride, 1 $\times$  complete protease inhibitory cocktail (Roche Molecular Biochemicals, Basel, Switzerland)] for 3 hours at 4°C with the anti-hMLH1 (6  $\mu$ g; BD PharMingen) or anti-hMLH3 (10  $\mu$ g; Santa Cruz Biotechnology) antibodies. The immunoprecipitates were captured by incubation for 30 minutes at 4°C with 50  $\mu$ L of 50% slurry of Protein A/G PLUS agarose (Santa Cruz Biotechnology). The agarose beads were then washed thrice with cold NP40 Lysis Buffer and the proteins were eluted with SDS sample buffer and subjected to Western blot analysis. Control experiments were done either in the absence of antibody or in the presence of 25 units of Benzonase (Merck, Whitehouse Station, NJ).

#### Analysis of the hMLH3 Promoter and Treatment of Cells with 5-Aza-2'-deoxycytidine

The hMLH3 5' flanking region was analyzed for CpG content with the CpG plot software of the European Bioinformatics Institute (<http://www.ebi.ac.uk/emboss/cpgplot/>) and its methylation status was evaluated with methylation-specific PCR as described previously (16). Primer sequences for the unmethylated reactions were 5'-GTTGTGTGTAGTTTTC-GGAGTTG-3' (sense) and 3'-CTCCACACCTAAACTAACA-3' (antisense),

which amplified a 229 bp product. The methylation-specific primers were 5'-CGCGTAGTTTTCGGAGTC-3' (sense) and 5'-CTAAACTAACGAAACG-CACG 3' (antisense), which amplified a 205 bp product. The PCR conditions are available on request.

To reactivate the expression of hMLH1 and hMLH3, 2.5  $\times$  10<sup>5</sup> HEK293T cells were seeded on a 78 cm<sup>2</sup> dish on day 0 and treated with 3  $\mu$ g/mL of 5-aza-2'-deoxycytidine (Fluka, Buchs, Switzerland) on days 2 and 5. The medium was changed 24 hours after each addition of the drug and the cells were harvested on day 8.

#### Microarray Experiments

Microarray experiments were done as described previously (27). Gray columns in the graphs represent mRNA levels based on raw signals detected in the corresponding cell lines with the Affymetrix HG-U133A microarray.

#### Mismatch Repair Assays

The assays were done as described previously (28, 29).

## Results

**Expression of hMutL $\gamma$  in Sf9 cells and production of anti-hMLH3 antibody.** To produce the recombinant hMLH3 and hMutL $\gamma$  factors, *S. frugiperda* Sf9 cells were infected with baculoviruses carrying cDNAs encoding hMLH1 and/or hMLH3. Infection of Sf9 cells with the hMLH3 virus alone yielded the protein in an amount that was hardly detectable by Western blotting. The amount of expressed protein was significantly increased when the cells were coinfecting with both hMLH1 and hMLH3 vectors (Fig. 1A), suggesting that the presence of hMLH1 is necessary for the stabilization of hMLH3 in Sf9 cells. This is reminiscent of hMSH6 and hPMS2, both of which require their heterodimeric partners (hMSH2 and hMLH1, respectively) for stability. However, the amount of the recombinant heterodimer obtained was too low

**Table 2.** Characteristics of the human cell lines used in this study

Cell lines	Origin	MMR status*	MMR protein defect <sup>†</sup>	Genetic complementation
293	Embryonic kidney epithelium	+		
293T	Embryonic kidney epithelium	—	<b>hMLH1, hPMS2, hMLH3</b>	
293T L $\alpha$ +	Embryonic kidney epithelium	+	<b>hMLH3</b>	<i>hMLH1</i> cDNA
CaCo2	Colon carcinoma	+		
CO115	Colon carcinoma	—	<b>hMLH1, hPMS2</b>	
Colo741	Colon carcinoma	+		
CX-1	Colon carcinoma	+		
GP5D	Colon carcinoma	—	<b>hMSH2, hMSH6, hMSH3, hMLH3</b>	
HCT116	Colon carcinoma	—	<b>hMLH1, hPMS2, hMSH3</b>	
HCT116+Ch3	Colon carcinoma	+	hMSH3	Chromosome 3
HT29	Colon carcinoma	+		
Hec1A	Endometrial adenocarcinoma	—	<b>hPMS2, hMSH6</b>	
Hec1A+Ch.7	Endometrial adenocarcinoma	—	<b>hMSH6</b>	Chromosome 7
HeLa	Cervical carcinoma	+		
HeLa clone 12	Cervical carcinoma	—	<b>hPMS2</b>	
LS411	Colon carcinoma	—	<b>hMLH1, hPMS2</b>	
SW48	Colon carcinoma	—	<b>hMLH1, hPMS2</b>	
SW480	Colon carcinoma	+		
SW837	Colon carcinoma	+		

\*+, MMR proficient; —, MMR deficient (these cell lines are unable to repair both base-base mismatches and insertion/deletion loops, with the exception of Hec1A+Ch.7, which is able to repair insertion/deletion loops).

<sup>†</sup>The primary alteration of MMR protein expression is reported in bold. Lack of hMLH1 or hMSH2 lead to proteolytic degradation of hPMS2, or hMSH6 and hMSH3, respectively. The *hMSH3* gene in HCT116 cells is mutated as a consequence of the MMR defect. The hMLH3 alterations are those described in this study; other alterations have been reported elsewhere (see text).

**Figure 1.** Expression of hMUTL3 in Sf9 cells, anti-hMUTL3 antibody specificity, and endogenous levels of hMUTL3 in colon cancer cell lines. **A**, expression of hMUTL3 in Sf9 cells infected either with a baculovirus vector expressing hMUTL3 or with a mixture of hMUTL1- and hMUTL3-expressing viruses. This Western blot shows that hMUTL3 is stabilized in this system by hMUTL1. **B**, Coomassie blue staining of rabbit polyclonal anti-hMUTL3 serum before (Serum) and after (Anti-hMUTL3) affinity purification. **C**, Western blot analysis of whole cell extracts of Sf9 cells uninfected (TE Ctrl, 2  $\mu$ g) or coinfecting with the hMUTL1/hMUTL3 baculoviruses (TE MUTL3, 2  $\mu$ g). The recombinant polypeptide (amino acids 961-1,453) used for the generation of the antibody was loaded in the third lane (1 ng). Anti-hMUTL3, affinity-purified serum used at 1:400 dilution; Pre-serum, preimmune serum used at the same dilution. **D**, microarray analysis of mRNA expression levels (top) and Western blot analysis of protein levels (bottom) of hMUTL3 in a series of colon cancer cell lines (50  $\mu$ g of whole cell extract per lane); n.s., nonspecific band detected by the anti-hMUTL3 antibody in human cell extracts.

to permit extensive purification. The reasons underlying the low levels of expression are unknown at this time, but it is possible that high amounts of the full-length protein may be toxic (7).

Commercially available antibodies could detect the recombinant hMUTL3 protein on Western blots but failed to detect the endogenous protein in all the human cell lines used in this study (data not shown). Therefore, we raised our own polyclonal rabbit antiserum, directed against the COOH terminus of hMUTL3, which contains the hMUTL1-interacting domain. The affinity-purified antibody (Fig. 1B) detected a band of the expected size (~160 kDa) in Sf9 lysates infected with the hMUTL1 and hMUTL3 vectors, whereas no signal was visible when we probed lysates of uninfected

cells (Fig. 1C). The purified antibody was then tested using extracts of various human colon cancer cell lines. The antibody highlighted a double band migrating at the expected size of hMUTL3 (Fig. 1D, bottom). As the faster migrating band was also observed in Western blots done with the preimmune serum (data not shown), and as the abundance of the slower-migrating band correlated with hMUTL3 mRNA expression levels in the same cell lines (Fig. 1D, top), we concluded that the latter is the specific band. As shown in Fig. 1D, the levels of hMUTL3 fluctuate significantly in the tested cell lines and seem to be independent of the amount of hMUTL1 and hPMS2 expressed in the same cells.

**Relative abundance of hMUTL3 in human cells and its interaction with hMUTL1.** Given that hMUTL3, hPMS2, and hPMS1 interact with the same region of hMUTL1 (30), we wanted to ask whether the relative abundance of the three different heterodimers can be correlated with the phenotype of the cells. Therefore, we did semiquantitative Western blots where we compared the intensity of bands due to endogenous hMUTL3 and hPMS2 proteins in HeLa cells with that of bands due to known amounts of the corresponding recombinant proteins (Fig. 2A). These experiments revealed that hMUTL3 is ~60 times less abundant than hPMS2. Considering that hPMS1 is ~10 times less abundant than hPMS2 in human cells (5), hMUTL3 exists in the cells at levels significantly

**Figure 2.** Relative abundance of hMUTL3 and its interaction with hMUTL1 in vivo. **A**, the recombinant hMUTL3 and hPMS2 proteins were loaded onto a denaturing polyacrylamide gel in the indicated amounts and visualized by Western blotting with the respective antibodies. The relative abundance of the two polypeptides was calculated by comparing the intensity of the hMUTL3 and hPMS2 bands with those of the endogenous proteins present in 50  $\mu$ g of HeLa whole cell extract. The blot is representative of two independent experiments, and the intensities of the bands were calculated by densitometry. **B**, coimmunoprecipitation of hMUTL3 and hMUTL1 in HeLa cells. One milligram of whole cell extract was incubated with or without 6  $\mu$ g of anti-hMUTL1 antibody (top) or 10  $\mu$ g of anti-hMUTL3 antibody (bottom). DNase, reaction done in the presence of 25 units of Benzonase. Ponceau staining for IgG is also shown to show equal loading. Ctrl, 50  $\mu$ g of HeLa whole cell extract.

**Figure 3.** Expression of hMLH3 *in vivo* is independent of hMLH1 and hPMS2 and can be controlled by cytosine methylation. **A**, microarray analysis of *hMLH3* mRNA (*top*) and protein (*bottom*) expression in hMLH1-deficient HCT116 and hPMS2-deficient Hec-1A cells. Correction of the MMR defect by transfer of chromosome 3 or 7, which carry wild-type copies of the *hMLH1* and *hPMS2* genes, respectively, had no effect on hMLH3 expression. **B**, hMLH3 expression is independent of hMLH1/hPMS2 expression in a panel of MMR-proficient and MMR-deficient cell lines. Legend as in (A). **C**, the *hMLH3* promoter in 293T cells is silenced by methylation. Expression of *hMLH1* in 293T-L $\alpha$  cells does not alter hMLH3 levels but demethylation of the promoter by 5-aza-2'-deoxycytidine (5-Aza-dC) treatment results in the reappearance of hMLH3, together with hMLH1, the promoter of which is also methylated in these cells. **D**, down-regulation of the *hMLH3* gene in GP5D cells is not mediated by cytosine methylation. The promoter was shown by methylation-specific PCR to be unmethylated and 5-Aza-dC did not reactivate hMLH3 expression in these cells. In the Western blot experiment, 50  $\mu$ g of total extract were used per lane.

lower than those of the other two hMLH1-interacting partners hPMS2 and hPMS1. In spite of this difference, hMLH3 was found to physically interact with hMLH1 in Far Western experiments (7) and in mammalian two hybrid assays (30). We could confirm this interaction using immunoprecipitation experiments in which the anti-hMLH1 antibody could immunoprecipitate both hMLH3 and hPMS2 from human cell lysates (Fig. 2B, *top*) and the anti-hMLH3 antibody precipitated the endogenous hMLH1 (Fig. 2B, *bottom*). No proteins were detected in control experiments where the precipitating antibody was omitted. The interaction between hMLH3 and hMLH1 was not mediated by bound DNA because treatment with DNase before incubation with the antibodies failed to abolish the interaction between the two proteins (Fig. 2B, *top*).

**hMLH1 is not required for the stability of hMLH3 in human cells.** hPMS2 and hPMS1 are stabilized by the presence of hMLH1 (1, 31). Considering this characteristic of these two MutL homologues, together with the finding that hMLH1 was required for the stabilization of hMLH3 in baculovirus-infected Sf9 cells (Fig. 1A), we expected to observe substantially decreased levels of endogenous hMLH3 in human cell lines lacking hMLH1. Surprisingly, we could detect hMLH3 in hMLH1-deficient HCT116 cells, and the restoration of hMLH1 expression by chromosome 3 transfer resulted in no appreciable increase in hMLH3 level (Fig. 3A, *bottom left*). This shows that the presence of hMLH1 is not required for hMLH3 stability in human cells. The relative amounts of intracellular hMLH3 were also unaffected by hPMS2 levels, as shown by comparison of hMLH3 band intensity in Western blots of extracts of the hPMS2-deficient Hec-1A cells with those of a Hec-1A clone in which the expression of hPMS2 was restored by chromosome 7 transfer (Fig. 3A, *bottom right*). hMLH3 protein levels failed to correlate with hMLH1 and hPMS2 expression also in other colon

cancer cell lines, such as SW480 or Caco2, that express both hMLH1 and hPMS2, or LS411, CO115, or SW48 that lack hMutL $\alpha$  (Fig. 3B).

Having established that the level of hMLH3 in cells is not dependent on hMLH1 but that it correlates well with *hMLH3* mRNA levels (Fig. 3B), we wondered whether the fluctuation of hMLH3 expression in the tested cell lines could be linked with cytosine methylation, which is known to silence several key genes in colon cancer (32). The human embryonic kidney cell line 293T is deficient in both hMLH1 and hMLH3 (Fig. 3C) and it could be shown that the CpG islands that constitute the promoters of hMLH1 (25) and other genes (33) are silenced by hypermethylation in these cells. As the *hMLH3* promoter also contains a CpG island, we reasoned that the lack of *hMLH3* expression in this cell line might also be linked to the transcriptional inactivation of its promoter. This prediction was substantiated in two independent experiments. First, treatment of 293T cells with the demethylating agent 5-aza-2'-deoxycytidine partially restored the expression of both hMLH1 and hMLH3 (Fig. 3C). In the second experiment, we treated genomic DNA of 293T and the parental 293 cells (which express both hMLH1 and hMLH3; Fig. 3C) with sodium bisulfite, which deaminates cytosines to uracils, but leaves 5-methylcytosines unchanged. Methylation-specific PCR showed that the promoter of the *hMLH3* gene in 293T cells was indeed methylated (data not shown). As expected, expression of high amounts of hMLH1 in the 293T-derived 293T L $\alpha$  cells resulted in the stabilization of hPMS2 (26) but did not affect hMLH3 levels (Fig. 3C). The promoter of the *hMLH3* gene can thus be silenced by cytosine methylation, but this is most likely not the only mechanism that results in the lack of expression of the protein, as 5-aza-2'-deoxycytidine treatment failed to induce the expression of hMLH3 in GP5D cells (Fig. 3D).

## Cancer Research

**Role of hMutL $\gamma$  in *in vitro* mismatch repair.** The observation that extracts from 293T-L $\alpha$  cells are MMR proficient (26) despite their lack of hMLH3 suggested that hMutL $\gamma$  does not play a major role in MMR *in vitro*. However, the possibility that it acts as a backup to hMutL $\alpha$  in the absence of hPMS2 could not be excluded. Therefore, we tested extracts of the human cell line HeLa clone 12, which expresses hMLH1, hPMS1, and hMLH3 but lacks hPMS2. As shown in Fig. 4A, these extracts were deficient in the repair of heteroduplex substrates containing either a G/T mismatch or an insertion/deletion loop of one or two nucleotides, but their repair proficiency on all tested substrates could be restored by the addition of recombinant hMutL $\alpha$ . Before concluding that hMutL $\gamma$  does not participate in MMR, we considered the possibility that the expression level of endogenous hMLH3 in the tested human cell lines might be too low to be detectably active in our *in vitro* assay. Therefore, we decided to test whether *in vitro* MMR activity may be detected in the presence of higher amounts of the heterodimer. These experiments were done with the hMutL  $\alpha$ ,  $\beta$ , and  $\gamma$  deficient extracts of 293T cells supplemented with whole cell extracts from

Sf9 cells expressing comparable amounts of hMutL $\alpha$  or hMutL $\gamma$  (Fig. 4B, inset). As shown previously, extracts of Sf9 cells overexpressing hMutL $\alpha$  could complement the MMR defect in the 293T extracts very efficiently, whereas extracts of uninfected Sf9 cells failed to do so (Fig. 4B; ref. 26). Interestingly, when extracts of Sf9 cells expressing hMutL $\gamma$  were used, we observed an increase in repair activity of ~20%. Similar results were obtained when the hMutL $\gamma$  was enriched by Ni-agarose chromatography, showing that the observed MMR activity was specific to hMutL $\gamma$ . We detected similar repair activities on substrates containing a G/T mismatch or a 1-base loop with a nick located either 5' or 3' from the mismatch, but no activity was observed on a substrate containing insertion/deletion loops of two or four nucleotides (Fig. 4B; data not shown). These experiments show that although physiologic levels of hMutL $\gamma$  are insufficient to mediate mismatch correction in our *in vitro* MMR assays, the factor can participate, albeit with low efficiency, in the correction of base-base mispairs and one-nucleotide insertion/deletion loops.

## Discussion

Like its *S. cerevisiae* homologue (8), the mammalian *MLH3* gene (7) could be shown to be involved in meiotic recombination (13–15). However, whereas the *S. cerevisiae* (8) and *Schizosaccharomyces pombe* (12) proteins play a small but distinct role in the repair of a subset of insertion/deletion loops, no similar evidence existed for mammalian MLH3. In this present study, we set out to search for this evidence.

We first wanted to study the expression of hMLH3 and confirm the existence of hMutL $\gamma$  *in vivo*. Using a newly generated antibody, we showed that hMLH3 is much less abundant than the other two known hMLH1 interactors, hPMS2 and hPMS1. Despite this, we could confirm the physical interaction between hMLH3 and hMLH1 in HeLa cells by immunoprecipitation experiments. Surprisingly, although hMLH1 was required for hMLH3 stability in Sf9 cells (Fig. 1A), no such requirement was apparent in human cells where no degradation of hMLH3 occurred in the absence of hMLH1 (Fig. 3A and B). We also failed to observe any significant competition between hMLH3 and hPMS2 for hMLH1, showing that in human cells hMLH3 might be stabilized by interaction with another, as yet unidentified, protein. This finding is supported by evidence from meiosis in mice, where Mlh3 was seen to bind to pachytene chromosomes before Mlh1 and, after Mlh1 recruitment to these sites, foci containing Mlh3 alone persisted (11, 15). It was, therefore, suggested that Mlh3 could either exist alone or interact with a different partner (11). Immunoprecipitation experiments revealed a direct interaction of *scMlh3p* with *Sgs1* helicase in meiotic *S. cerevisiae* cells (34) and hMLH3 was shown to bind hMSH4 in meiotic human cells (14); however, the identification of the putative hMLH3 partners that might help stabilize it in mitotic cells must await the results of future experiments.

The ultimate objective of this work was to elucidate the role of hMLH3 in human MMR. We first tested extracts of human HeLa clone 12 cells, which lack hPMS2 (22) and thus contain only hMutL $\beta$  and hMutL $\gamma$ . As the former heterodimer is devoid of MMR activity in our *in vitro* MMR assay (31), any observed repair activity could be ascribed to hMutL $\gamma$ . The extracts were MMR deficient on all tested substrates (Fig. 4A), which suggested that the hMutL $\gamma$  heterodimer does not participate in MMR. However, as hMLH3 is generally much less abundant in human cells than hPMS2, we

**Figure 4.** *In vitro* MMR assays. A, the MMR defect of cytoplasmic extracts of the hPMS2-deficient cell line HeLa clone 12 can be corrected by the addition of 0.2  $\mu$ g purified hMutL $\alpha$ . The repair efficiencies were determined on heteroduplex substrates containing a G/T mismatch, or +1 ( $\Delta 1$ ) or +2 ( $\Delta 2$ ) insertion/deletion loops. B, cytoplasmic extracts of 293T cells, which lack hMLH1, hMLH3, and hPMS2 were supplemented with 2  $\mu$ g of whole cell extract from Sf9 cells coinfecting with hMLH1/hPMS2 (Sf9-L $\alpha$ ), hMLH1/hMLH3 (Sf9-L $\gamma$ ), or the latter partially purified on Ni-agarose (Sf9-L $\gamma$ -N). MMR efficiency was tested on heteroduplex substrates containing a G/T mismatch, or +1 ( $\Delta 1$ ) or +2 ( $\Delta 2$ ) insertion/deletion loops. The amounts of hMutL $\alpha$  and hMutL $\gamma$  complexes used for complementation were comparable (inset). Whole cell extracts from uninfected Sf9 cells (Sf9) or Sf9 extract that underwent Ni-agarose (Sf9-N) chromatography were used as negative controls. Columns, result of at least three independent experiments; bars, SE. Cytoplasmic extract of the MMR-proficient HeLa cells was used as the positive control.

wanted to exclude the possibility that the lack of repair activity is linked to insufficient amounts of hMutL $\gamma$ . Therefore, we tested the MMR activity of extracts of 293T cells, which are deficient in all three MutL homologues, supplemented either with recombinant hMutL $\alpha$  or hMutL $\gamma$  (Fig. 4B). The former factor complemented the MMR defect in the 293T extracts on all tested substrates. When comparable amounts of hMutL $\gamma$  were used, we observed a small but significant (~20%) repair with both G/T and +1 insertion/deletion loop substrates. This repair activity was not due to an intrinsic repair activity of the Sf9 extracts per se, as extracts from uninfected Sf9 cells were repair deficient in the complementation experiments. As there are no available functional assays to test the activity of hMutL $\gamma$ , a possibility exists that this heterodimer was isolated in a partially inactive form. However, we consider this possibility unlikely because all the procedures used were identical to those used for the preparation of the Sf9 extract expressing hMutL $\alpha$ , which was fully active. Moreover, immunoprecipitation experiments done with Sf9 extracts expressing hMutL $\gamma$  showed that hMLH3 was able to bind hMLH1 (data not shown). The sensitivity of the *in vitro* MMR assay remains, however, rather low so that the contribution of hMutL $\gamma$  to the repair process *in vivo* might be higher. Interestingly, the repair activity of hMutL $\gamma$  was limited to G/T mismatch and 1-base loops, as we failed to observe any repair activity using +2- and +4-base-loop substrates. The latter result indicates that hMutL $\gamma$  seems to be involved in the repair of substrates recognized by hMutS $\alpha$  rather than insertion/deletion loops of more than one extrahelical nucleotide recognized by hMutS $\beta$ . This is in contrast to the data obtained in *S. cerevisiae* where the role of *scMlh3p* seems to be involved in the repair of a subset of insertion/deletion loops together with *scMutS $\beta$* . The role of hMLH3 in mammals thus might differ from that in lower eukaryotes.

Our findings, suggesting that hMutL $\gamma$  may play a backup role in human MMR, are supported by evidence from the mouse model. As noted above, *Mlh3 null* mice were not cancer prone in the first 9 months of life and showed no gross defects in MMR (15). However, a long-term study of these animals, coupled with a highly sensitive analysis of their genomic DNA, provides evidence for the involvement of *Mlh3* defects in both MMR and tumorigenesis. *Mlh3*<sup>-/-</sup> mice have a shorter life span than the wild-type controls and more than half of the animals develop cancers, including gastrointestinal tumors after the 9-month time span. Importantly, *Mlh3* deficiency increased the levels of

mutations in long mononucleotide repeats, although to a lesser extent than in *Pms2*<sup>-/-</sup> mice (35). Taken together, our results and the mouse model data suggest that the hMutL $\gamma$  heterodimer functions in the repair of base-base mismatches and small insertion/deletion loops.

Considering the possible involvement of hMLH3 in human MMR, the identification of hMLH3 silencing through promoter hypermethylation is of particular interest. We showed that the hMLH3 promoter is methylated in 293T cells and that the protein is consequently not expressed. In this particular cell line, the methylation could be caused by the presence of the SV40 large T antigen. However, using methylation-specific PCR, we could detect partially methylated hMLH3 promoters in the colon cancer cell line LS411 and in the ovarian cancer cell line A2780/CP70, and fully methylated in the leukemia cell line Jurkat (data not shown), which shows that hMLH3 silencing via promoter hypermethylation can also be unrelated to the presence of SV40 large T antigen.

Although recombinant hMutL $\gamma$  possessed detectable repair activity in our *in vitro* MMR assays, hPMS2-deficient cells expressing hMLH3 display a strong mutator phenotype (refs. 16, 23; this study). This suggests that hMLH3, most likely in the form of hMutL $\gamma$ , does not play a major role in MMR *in vivo*. However, the detection of sequence variants of hMLH3 in the germ line of families predisposed to colorectal cancer (17, 20), coupled with our detection of epigenetic silencing of hMLH3 in human cell lines, suggests that this gene may play a role in human cancer, possibly in combination with other risk factors. If hMutL $\gamma$  does indeed play a backup role for hMutL $\alpha$  *in vivo*, the fluctuating abundance of hMLH3, such as that observed in the tested cell lines (Figs. 1 and 3), might help explain the variable penetrance of hPMS2 mutations in hereditary nonpolyposis colon cancer families (16).

## 7. Acknowledgements

I would like to thank Prof. Josef Jiricny for giving me the possibility to make my thesis at his institute, and for his excellent, and always stimulating, scientific discussions and advices.

I would like to specially thank Dr. Giancarlo Marra for the excellent supervision and guidance of my projects.

My sincere gratitude to all the institute members I have met over these years, especially to those that have contributed to the results presented in this thesis.

Special thanks to my lab mates Anne Anstett, Elda Cannavo, Elisa Cattaneo, Ritva Haider and Emilija Veljkovic for creating a wonderful atmosphere and for their unconditional support whenever I needed.

I am glad to have shared fantastic moments and conversations with Stefano Ferrari, Franziska Fisher, Marianne Köpfler, Giancarlo Marra, Elisabetta Pani, Helga Pletscher, Kanagaraj Radhakrishnan, Malika Salah, Silvia Schanz, Anne Muller and, very especially, with Elda Cannavo, Elisa Cattaneo, Petr Cejka, Mahmoud El-Shemerly, Javier Peña Díaz, Emanuele Valtorta, and Emilija Veljkovic. You are all very nice persons.

Many thanks to former and present technical assistants for their efficient effort which enormously facilitates our research work: Helga Pletscher, Marianne Grima, Marianne Köpfler, Jana Rojickova, Patrick Greiner, Margaret Fäsi, Ritva Haider, Christine Hemmerle, Christiane König, Ester Kohler, Christoph Moser, Malika Salah, Najat Maanaoui-Salah, Farah M'Hamedi-Baccouche, and Peter Binz.

I would like to emphasize the great assistance received from Marzana Künzli-Gotarczyk, Endre Laczko, Andrea Patrignani, Hubert Rehrauer and Ulrich Wagner at the FGCZ. Thank you very much for your help and patience.

I would like to thank and recognize the awesome contribution to this work done by all our collaborators, especially Mariagrazia de Palo and Laurens Van der Flier. It is a pleasure to work with you.

I would also like to thank Alex Gil-Vernet for the great time we had together in Zurich. I will always remember how much fun we had in “La Peña” watching the Barça games!!!!... We have to start with it again when we definitely come back to Barcelona.

Thanks to Ignacio Fernández de las Nieves (Nachorrrrrrr!) for the great moments and lots of fun we had together (the “Squash Battles” were memorable!!!). To discuss with you was always a pleasure and my little knowledge about Organic Chemistry is thanks to you... jejejejejeje!!!!.

Thanks to Patricia Fletcher for her help and patience with my English, I really appreciate it.

Many many thanks to those FRIENDS who have kept in touch, despite the distance, and/or have come to visit us to Zürich: Marc Oliveras, Albert Ramón & Mar, Carolina Mordillo, Cristina Vilella & Borja, Alex Gil-Vernet & Anna, Fadhel Ben Chaabane, Reinaldo Fraga, Albert Nebra, Ernest Millán, Xavier Rubiralta, Alberto Román, Nestor Busquets, and Alfonso Chico de Guzmán. It has been really nice from you.

Thanks to my family for their constant and total support that helped me to get so far. Thanks to have made me feel so close being so far. Thanks to: i) my mother, Roser, for her curiosity about my

research work and for her interesting critical point of view, ii) my father, Ramón, to make little things unforgettable, like a breakfast at Mövenpick, with his enthusiasm, iii) my brother, Aaron, and his wonderful family; Marta, Rita and Ramón Jr. because I feel extremely happy everytime I see them, iv) my sister, Raquel, and Joan for having me punctually informed about what is going on in Barcelona via “Radio Macuto”, v) my sister, Carla, and Carles to have created such a nice creature: Vico, and vi) Nestor (yes, you are part of the family... jejejejeej!!!) because our friendship is so strong that I am sure it will last forever. Of course, thanks to all of you to have made it to come to my defense, it was very important for me.

Finally, thanks to Carlota. Gràcies per ser com ets (dolça, divertida, intel·ligent, tenaç, emprenedora, guapa, carinyosa, amb caràcter... en definitiva... meravellosa!!!) i per estimar-me com m'estimes. Compartir la meua vida amb tu es el millor que em podia passar. Em fas sentir la persona més afortunada d'aquest món... Tatimu.

## 8. Curriculum Vitae

### Personal Information

First name      Jacob  
Last name        Sabatés Bellver  
Date of birth    7<sup>th</sup> October 1978  
Place of birth   Barcelona, Spain  
Nationality      Spanish

### Education

1984-1998      High school: Institut Tècnic Eulàlia, Barcelona, Spain

1991             High school: Vicente Cañada Blanch, London, UK

1998-2003      University: **Licensed in Biotechnology** (10 semesters), Universitat Autònoma de Barcelona, Barcelona, Spain

2003             Diploma thesis: **“Bioalcohol production by *S.cerevisiae* at high cellular densities in a two-stage bioreactor with recirculation of biomass through membranes”**  
(1 semester), Department de Génie Biochimique et Alimentaire (GBA), Laboratoire Biotechnologie-Bioprocédés (LBB), Institute National des Sciences Appliquées (INSA), Toulouse, France. Supervised by Dr.Carole Molina-Jouve and Prof. Dr. Gérard Goma

2003-2006      PhD studies: **“The Transcriptome of Epithelial Transformation in the Distal Gastrointestinal Tract”** (7 semesters), Institute of Molecular Cancer Research of Zürich (IMCR), University of Zürich, Zürich, Switzerland. Supervised by Dr. Giancarlo Marra and Prof. Dr. Josef Jiricny
